Has Medical Innovation Reduced Cancer Mortality?

Frank R. Lichtenberg*

*Columbia University (New York, NY) and National Bureau of Economic Research (Cambridge, MA). e-mail: frank.lichtenberg@columbia.edu

Abstract

I analyze the effects of four types of medical innovation and cancer incidence on US cancer mortality rates during the period 2000–2009, by estimating difference-in-differences models using longitudinal (annual) data on ~60 cancer sites (breast, colon, etc.). The outcome measure used is not subject to lead-time bias. I control for mean age at diagnosis, the stage distribution of patients at time of diagnosis, and the sex and race of diagnosed patients. Under the assumption that there were no pre-dated factors that drove both innovation and mortality and that there would have been parallel trends in mortality in the absence of innovation, the estimates indicate that there were three major sources of the 13.8% decline of the age-adjusted cancer mortality rate during 2000–2009. Drug innovation and imaging innovation are estimated to have reduced the cancer mortality rate by 8.0 and 4.0%, respectively. The decline in incidence is estimated to have reduced the cancer mortality rate by 1.2%. The social value of the reductions in cancer mortality attributable to medical innovations has been enormous, and much greater than the cost of these innovations. (JEL codes: C23, J11, I12, O33)

Keywords: cancer, neoplasm, mortality, longevity, innovation, chemotherapy, diagnostic imaging, radiation, surgery

1 Introduction

The cost of cancer care is substantial, and increasing. In 2010, the direct cost of US cancer care was \$125 billion (almost \$9000 per cancer patient). This figure does not include indirect costs, such as lost productivity, which add to the overall financial burden of cancer. According to researchers at the National Cancer Institute (Mariotto et al. 2011, Yabroff et al. 2008, National Cancer Institute 2013a,b), in the absence of any change in the cost per patient of cancer care, changes in the US population alone will result in a real cost increase of 27%, to \$155 billion, by 2020. However, if costs in the initial and final phases of care increase by 2% annually, e.g. due to advances in diagnostic technology and novel targeted treatments, the total cost of care in 2020 will be \$173 billion, an increase of 40% from 2010. If costs increase by 5% annually, the total cost of care in 2020 will be \$207 billion, an increase of 68% from 2010. Thus, medical innovation during the period 2010–2020 may increase the direct cost of US cancer care by \$52 billion in 2020. More generally, the Congressional Budget Office (2008, Preface) stated that 'the largest single factor driving [healthcare] spending growth [is] the greatly expanded capabilities of medicine

brought about by technological advances in medical science over the past several decades'. ¹

As noted by the Australian Productivity Commission (2005), even if advances in medical technology drive increased healthcare expenditure, the critical question is whether the benefits outweigh the costs. In other markets, increased expenditure generally would indicate increased consumer benefits. But because the direct purchase of healthcare is mostly undertaken by third parties—governments and private health insurers—normal market tests for ensuring value for money generally do not apply. Although assessing the benefits of medical innovation—its impact on health outcomes—is as important as assessing the costs—its impact on health expenditure—the Commission (2005, p. 99) noted that 'most formal studies…have focused on the expenditure impacts of medical technology, partly because costs are more easily identified and quantified than are benefits'.

In this article, I will analyze the effects of medical innovation on US cancer mortality rates. During the period I will study (1996–2009), the age-adjusted cancer mortality rate declined 19%; the age-adjusted cancer incidence rate declined by only 4%. Lakdawalla et al. (2010) quantified the value of gains in cancer survival, and analyzed the distribution of value among various stakeholders. They estimated that, between 1988 and 2000, life expectancy for cancer patients increased by roughly 4 years, and the average willingness-to-pay for these survival gains was roughly \$322,000. Improvements in cancer survival during this period created 23 million additional life-years and roughly \$1.9 trillion of additional social value. However, Lakdawalla et al. (2010) did not identify the source of these gains, or determine the extent to which they were due to innovation in cancer treatment.

A randomized clinical trial (RCT) undoubtedly provides the most reliable evidence about the impact of a specific treatment innovation (e.g. new drug or diagnostic procedure) on mortality or survival from a specific type of cancer. Therefore, to conduct an overall assessment of the impact of medical innovation on cancer mortality, one might consider performing a meta-analysis of data from RCTs. But that approach seems unlikely to be

However, this conclusion was based on studies that may have not fully accounted for spillovers across episodes of care or medical conditions. Such spillovers may be important: a recent study of a cohort of US Medicare beneficiaries aged 65 years and older with a diagnosis of cataract found that patients who had cataract surgery had lower odds of hip fracture within 1 year after surgery compared with patients who had not undergone cataract surgery (Tseng et al. 2012). Also, Lichtenberg (2011) found that US states that adopted new drugs and diagnostic imaging procedures more rapidly had larger gains in life expectancy during the period 1991–2004, but that they did not have larger increases in per capita medical expenditure, controlling for other factors.

fruitful, for several reasons. The sheer number of studies that would need to be considered is overwhelming: PubMed contains > 29,000 articles that address both cancer mortality and just one type of cancer treatment: drug therapy.² The metrics used in these studies are likely to be quite heterogeneous. As Thaul (2012, p. 4) observes, a drug's 'effectiveness'—how well it works in a real-world situation—may differ from its 'efficacy'—whether a drug demonstrates a health benefit over a placebo or other intervention when tested in an ideal situation, such as a tightly controlled clinical trial. And the overall impact of medical innovation on cancer mortality depends on the extent to which various treatments are used, as well as on the effectiveness of each treatment.

Rather than performing a meta-analysis of RCTs, I will perform an original analysis of observational data on cancer treatment, incidence, and mortality. The data I will analyze—longitudinal (annual) data on ~60 cancer sites (breast, colon, etc.)—are aggregate data, rather than patient-level data. The patient-level data sets to which I have access do not include adequate information on both treatment and mortality. Even if patient-level data on both treatment and mortality were available, Stukel et al. (2007) argue that comparisons of outcomes between patients treated and untreated in observational studies may be biased due to differences in patient prognosis between groups, often because of unobserved treatment selection biases. I believe that difference-in-differences estimates based on aggregate panel data are much less likely to be subject to unobserved treatment selection biases than estimates based on cross-sectional patient-level data.⁴

Several previous studies have examined the overall impact of medical innovation on cancer mortality.⁵ These studies were subject to several limitations. First, the outcome measure in all of these studies was the cancer survival rate—the proportion of patients alive at some point subsequent to the diagnosis of their cancer—and this measure may be

The following PubMed search yielded 29,699 results (articles): ((neoplasms[MeSH Major Topic]) AND ("drug therapy"[MeSH Subheading])) AND ("mortality"[MeSH Subheading]).

The data set I use to obtain treatment information (the MEDSTAT MarketScan database) includes only inpatient mortality data. The majority of deaths occur outside the hospital (http://www.cdc.gov/nchs/data/dvs/Mortfinal2005_worktable_309.pdf). Moreover, if a person disenrolls from a health plan covered by MarketScan after he or she is treated, his or her death would not be observed, either inside or outside the hospital.

Jalan and Ravallion (2001) argued that 'aggregation to village level may well reduce measurement error or household-specific selection bias' (p. 10).

Lichtenberg (2008, 2009a,b) examined the effect of pharmaceutical innovation on relative cancer survival rates, controlling for variables likely to reflect changes in probability of diagnosis (e.g. age at diagnosis, cancer stage of diagnosis, and number of people diagnosed).

subject to lead-time bias. Second, only one kind of medical innovation—chemotherapy innovation—was usually analyzed, and this was usually measured by the number of drugs potentially available to cancer patients, rather than by the drugs actually used by them.

This article builds on previous research in several ways. First, the outcome measure I use—the *unconditional* cancer mortality rate (the number of deaths, with cancer as the underlying cause of death, occurring during a year per 100,000 population)—is not subject to lead-time bias. Second, I analyze the effects of four important types of medical innovation—chemotherapy, 6 diagnostic imaging, radiotherapy, and surgical innovation—and cancer incidence rates on cancer mortality rates. Third, my measures of medical innovation are based on extensive data on treatments given to large numbers of patients with different types of cancer.

In Section 2, I will briefly review the history of several types of medical innovation, and discuss recent trends in cancer incidence and mortality. In Section 3, I will present the econometric model I will estimate to assess the impact of medical innovation on cancer mortality. Data sources and descriptive statistics will be discussed in Section 4. Estimates of cancer mortality models will be presented in Section 5. The implications of the estimates will be discussed in Section 6.

2 Brief review of history of medical innovation, and recent trends in cancer incidence and mortality

In this section, I will first briefly review the history of three types of medical innovation: chemotherapy, diagnostic imaging, and radiation therapy. Then I will discuss recent trends in cancer incidence and mortality.

2.1 Chemotherapy

Chabner and Roberts (2005) and DeVita and Chu (2008) provide useful accounts of the history of chemotherapy. According to DeVita and Chu (2008), the use of chemotherapy to treat cancer began at the start of the 20th century with attempts to narrow the universe of chemicals that might affect the disease by developing methods to screen chemicals using transplantable tumors in rodents. It was, however, four World War II–related

138

I will analyze the impact of innovation in drugs administered by providers, not innovation in self-administered drugs, because provider-administered drug claims contain diagnosis codes, but self-administered drug claims do not. Data from MEDSTAT MarketScan and IMS Health's National Sales Perspectives indicate that ~70% of cancer drug expenditure is on drugs administered by providers. Only 10% of expenditure on other (non-cancer) drugs is on drugs administered by providers.

programs, and the effects of drugs that evolved from them, that provided the impetus to establish in 1955 the national drug development effort known as the Cancer Chemotherapy National Service Center. The ability of combination chemotherapy to cure acute childhood leukemia and advanced Hodgkin's disease in the 1960s and early 1970s overcame the prevailing pessimism about the ability of drugs to cure advanced cancers, facilitated the study of adjuvant chemotherapy, and helped foster the national cancer program. Today, chemotherapy has changed as important molecular abnormalities are being used to screen for potential new drugs as well as for targeted treatments.

Chabner and Roberts (2005) say that the beginnings of the modern era of chemotherapy can be traced directly to the 1942 discovery of nitrogen mustard as an effective treatment for cancer. Their history of chemotherapy timeline includes the following five milestones during the period 1975–2004:

- 1975: A combination of cyclophosphamide, methotrexate, and fluorouracil (CMF) was shown to be effective as adjuvant treatment for nodepositive breast cancer.
- 1978: The Food and Drug Administration (FDA) approved cisplatin for the treatment of ovarian cancer, a drug that would prove to have activity across a broad range of solid tumors.
- 1992: The FDA approved paclitaxel (Taxol), which becomes the first 'blockbuster' oncology drug.
- 2001: Studies by Brian Druker led to FDA approval of imatinib mesylate (Glivec) for chronic myelogenous leukemia, a new paradigm for targeted therapy in oncology.
- 2004: The FDA approved bevacizumab (Avastin), the first clinically proven antiangiogenic agent, for the treatment of colon cancer.

The pace of chemotherapy innovation has increased sharply during the past 2 decades. Data from IMS Health indicate that, by the end of 2009, cancer drugs (EphMRA/PBIRG Anatomical Classification L: antineoplastic and immunomodulating agents) used in the USA contained 133 distinct molecules. Twenty of these drugs had been launched by the end of 1969, and 49 had been launched by the end of 1989. Thus, the number of new cancer molecules launched during 1990–2009 (84 = 133 - 49) was almost three times as large as the number of new cancer molecules launched during 1970–1989 (29 = 49 - 20).

Pharmaceuticals are more research-intensive than other types of medical care: in 2007, prescription drugs accounted for 10% of US health expenditure (Center for Medicare and Medicaid Services 2013a; Table 2), but

more than half of US funding for biomedical research came from pharmaceutical and biotechnology firms (Dorsey et al. 2010). Moreover, new drugs often build on upstream government research (Sampat and Lichtenberg 2011).

2.2 Diagnostic imaging

Bradley (2008) provides a useful survey of the history of medical imaging. He argues that computers really entered the world of medical imaging in the early 1970s with the advent of computed tomography (CT scanning) and then magnetic resonance imaging (MRI). CT was a major advance that first allowed multiple tomographic images (slices) of the brain to be acquired. Before the advent of CT in 1973, we had only plane films of the head (which basically just show the bones) or angiography (which only suggests masses when the vessels of the brain are displaced from their normal position). Basically there was no way to directly image the brain. Today's multidetector row CTs acquire multiple submillimeter spatial resolution slices with processing speeds measured in milliseconds rather than hours. MRI also evolved during the 1970s, initially on resistive magnets with weak magnetic fields, producing images with low spatial resolution. Even then, however, it was obvious that the soft-tissue discrimination of MRI was superior to that of CT, allowing earlier diagnoses. MRI also had the advantage that it did not require ionizing radiation like X-ray-based CT.

As stated by the National Cancer Institute (2013c) imaging, by itself, is not a treatment, but can help in making better decisions about treatments. The same imaging technique can help doctors find cancer, tell how far a cancer has spread, guide delivery of specific treatments, or find out if a treatment is working...Imaging can be used to make cancer treatments less invasive by narrowly focusing treatments on the tumors. For instance, ultrasound, MRI, or CT scans may be used to determine exact tumor locations so that therapy procedures can be focused on the tumor, minimizing damage to surrounding tissue...Imaging can be used to see if a previously treated cancer has returned or if the cancer is spreading to other locations.

2.3 Radiation therapy

The American Society for Radiation Oncology (2013) provides a brief survey of the history of radiation therapy. It is clear from this that recent advances in radiation therapy have been facilitated or enabled by advances in diagnostic imaging. Medicine has used radiation therapy as a treatment for cancer for > 100 years, with its earliest roots traced from the

discovery of X-rays in 1895 by Wilhelm Röntgen. Emil Grubbe of Chicago was possibly the first American physician to use X-rays to treat cancer, beginning in 1896. The field of radiation therapy began to grow in the early 1900s largely due to the groundbreaking work of Nobel Prize—winning scientist Marie Curie (1867–1934), who discovered the radioactive elements polonium and radium in 1898. This began a new era in medical treatment and research. Radium was used in various forms until the mid-1900s, when cobalt therapy and cesium units came into use. Medical linear accelerators have been used too as sources of radiation since the late 1940s.

With Godfrey Hounsfield's invention of CT in 1971, three-dimensional (3-D) planning became a possibility and created a shift from two-dimensional to 3-D radiation delivery. CT-based planning allows physicians to more accurately determine the dose distribution using axial tomographic images of the patient's anatomy. Orthovoltage and cobalt units have largely been replaced by megavoltage linear accelerators, useful for their penetrating energies and lack of physical radiation source.

The advent of new imaging technologies, including MRI in the 1970s and positron emission tomography in the 1980s, has moved radiation therapy from 3-D conformal to intensity-modulated radiation therapy and to image-guided radiation therapy tomotherapy. These advances allowed radiation oncologists to better see and target tumors, which has resulted in better treatment outcomes, more organ preservation, and fewer side effects.

2.4 Recent trends in cancer incidence and mortality

Data on rates of incidence of and mortality from all malignant cancers are shown in Figure 1. Cancer incidence and mortality were both increasing between 1973 and the early 1990s, but have declined since then. The change in cancer mortality during the period 1996-2009 (the period covered by my econometric analysis) has varied considerably across cancer sites, whether or not we control for the change in incidence. Figure 2 presents data on the 1996-2009 log change in the mortality rates of the 10 largest cancer sites (ranked by their average mortality rate during 1985–2009). The red bars show the simple log change in the mortality rate, i.e. ln(mort_{i,2009}/mort_{i,1996}), where mort_{it} is the age-adjusted mortality rate from cancer at site i in year t. The change in cancer mortality ranged between -39% (= $\exp(-0.49) - 1$) for prostate cancer and +3% for pancreatic cancer. The blue bars show the residual from the simple regression of ln(mort_{i,2009}/mort_{i,1996}) on ln(inc_{i,2009}/inc_{i,1996}), where inc_{it} is the ageadjusted incidence rate of cancer at site i in year t. The change in cancer mortality, adjusted for the decline in incidence, ranged between -25% for prostate cancer and +16% for pancreatic and urinary bladder cancers. Figure 3 shows annual data on the age-adjusted mortality rates of six

Figure 1 Age-adjusted cancer incidence and mortality rates, 1973-2009.

Figure 2 Log change in age-adjusted mortality rate, 1996-2009, top 10 cancer sites (ranked by average mortality rate).

major cancer sites during 1996–2009. In the next section, I will present an econometric model for testing the hypothesis that cancer sites experiencing more medical innovation tended to have larger reductions in mortality rates.

3 Econometric model to assess the impact of medical innovation on cancer mortality

To assess the impact of medical innovation on cancer mortality, I will estimate difference-in-differences models using longitudinal (annual) data on $\sim\!60$ cancer sites (breast, colon, etc.). The dependent variable in these models will be $ln(mort_rate_{st})$, where $mort_rate_{st}$ is the age-adjusted mortality rate from cancer at site s in year t. The explanatory variables will be current and lagged measures of the $vintage^8$ of drug, imaging, radiotherapy, and surgery treatments for cancer at site s in year t; current and lagged values of $ln(inc_rate_{st})$, where lnc_rate_{st} is the age-adjusted incidence rate of cancer at site s in year t; and current and lagged values of several variables that should reflect case mix, illness severity, and cancer stage at time of diagnosis:

- mean age at diagnosis
- stage distribution of patients at time of diagnosis: the fractions of patients with (1) in situ, (2) localized or regional, and (3) distant cancers. (The omitted category is unstaged cancers.)
- the fraction of diagnosed patients who were male
- the fraction of diagnosed patients who were white

I assume that there were no pre-dated factors that drove both vintage and mortality, and that there would have been parallel trends in mortality in the absence of innovation. Direct testing of this assumption (e.g. by comparing the pre-trends of early and late adopters or of deep/non-deep new technology implementers) is difficult, because, as shown later, medical innovation is a continuous process, not a discrete process. As I control

According to the Merriam Webster dictionary, one definition of vintage is 'a period of origin or manufacture (e.g. a piano of 1845 vintage)'. http://www.merriam-webster.com/dictionary/vintage

144

The coefficient on $\ln(inc_{i,2009}/inc_{i,1996})$ in this regression is 0.385 (*t*-statistic = 3.50; *p*-value = 0.0009). R^2 = 0.1604; N = 66. The equation was estimated by weighted least-squares, weighting by the cancer site's average mortality rate during 1985–2009.

When an intervention (or policy change) being analyzed is discrete, e.g. in Galiani et al.'s (2005) study of the impact of privatization of water services on child mortality in Argentina, analysis of pre-trends is feasible and appropriate.

Figure 3 Age-adjusted mortality rate, six major cancer sites, 1996–2009 (index: 1996 = 1.00).

for the current and lagged incidence rate and several variables that should reflect case mix, illness severity, and cancer stage at time of diagnosis, I believe that this assumption is very likely to be satisfied. Before describing the specific models I will estimate, I will provide justifications for my choices of dependent and explanatory variables.

Two types of statistics are often used to assess progress in the 'war on cancer': survival rates and mortality rates. Survival rates are typically expressed as the proportion of patients alive at some point subsequent to the diagnosis of their cancer. For example, the observed 5-year survival rate is defined as follows:

5-year survival rate = number of people diagnosed with cancer at time t alive at time t + 5/number of people diagnosed with cancer at time t

= 1 - (number of people diagnosed with cancer at time t dead at time t + 5/ number of people diagnosed with cancer at time t)

Hence, the survival rate is based on a *conditional* (on previous diagnosis) mortality rate. The second type of statistic is the *unconditional* cancer mortality rate: the number of deaths, with cancer as the underlying cause of death, occurring during a year per 100,000 population.

The 5-year relative survival rate from cancer has increased steadily since the mid-1970s, from 49.1% for people diagnosed during 1975-1977 to 67.6% for people diagnosed during 2001–2008. Although this increase suggests that there has been significant progress in the war against cancer, it might simply be a reflection of (increasing) lead-time bias. Lead-time bias is the bias that occurs when two tests for a disease are compared, and one test (the new, experimental one) diagnoses the disease earlier, but there is no effect on the outcome of the disease—it may appear that the test prolonged survival, when in fact it only resulted in earlier diagnosis when compared with traditional methods. Epidemiologists have argued that while 5-year survival is a perfectly valid measure to compare cancer therapies in a randomized trial, comparisons of 5-year survival rates across time (or place) may be extremely misleading. If cancer patients in the past always had palpable tumors at the time of diagnosis, whereas current cancer patients include those diagnosed with microscopic abnormalities, then 5-year survival would be expected to increase over time even if new screening and treatment strategies are ineffective. Therefore, to avoid the problems introduced by changing patterns of diagnosis, progress against cancer should be assessed using unconditional mortality rates. 10

-

I will control for cancer incidence (by including it in the mortality equation), but in a completely unrestrictive manner. If changes in incidence are merely due to lead-time bias, the coefficient on incidence should be 0.

The unconditional cancer mortality rate is essentially the unconditional probability of death from cancer (P(death from cancer)). The law of total probability implies the following:

 $P(\text{death from cancer}) = P(\text{death from cancer} \mid \text{cancer diagnosis})*$ $P(\text{cancer diagnosis}) + P(\text{death from cancer} \mid \text{no cancer diagnosis})* \quad (1)$ (1 - P(cancer diagnosis))

If the probability that a person who has never been diagnosed with cancer dies from cancer is quite small (P(death from cancer | no cancer diagnosis) ≈ 0), which seems plausible, ¹¹ this reduces to

P(death from cancer)
$$\approx$$
 P(death from cancer | cancer diagnosis)*
P(cancer diagnosis)
(2)

Hence

$$\label{eq:problem} \begin{split} & \ln\,P(\text{death from cancer}\,|\,\,\text{cancer}\,\,\text{diagnosis}) \\ & + \ln\,P(\text{cancer diagnosis}) \end{split}$$

(3)

I hypothesize that the conditional mortality rate (P(death from cancer | cancer diagnosis)) is inversely related to the average (current and lagged) quality of medical procedures. ¹² The quality of procedures is not directly observable. However, I also hypothesize that, in general, the average quality of newer (later vintage) procedures is higher than that of older (earlier vintage) procedures. The hypotheses that vintage has a positive effect on quality, and that quality has a negative effect on mortality, imply that vintage has a negative effect on mortality, i.e. that $\beta < 0$ in the following equation:

In P(death from cancer | cancer diagnosis) = β treatment vintage (4)

Solow (1960) introduced the concept of vintage into economic analysis. This was one of the contributions to the theory of economic growth that the Royal Swedish Academy of Sciences cited when it awarded Solow the 1987 Alfred Nobel Memorial Prize in Economic Sciences:

Solow's basic idea was that technical progress is 'built into' machines and other capital goods and that this must be taken into account when

12 The average quality of imaging procedures may also affect the probability of diagnosis.

147

The cancer incidence rate is 2.5 times as high as the cancer mortality rate: 2006 US age-adjusted incidence and mortality rates were 456.2 and 181.1, respectively. Because the probability of dying from cancer is much lower than the probability of being diagnosed with cancer, P(death from cancer | no cancer diagnosis) is likely to be small.

making empirical measurements of the role played by capital. ¹³ This idea then gave birth to the 'vintage approach'...Solow's empirical results naturally gave the formation of capital a markedly higher status in explaining the increase in production per employee... the vintage capital concept... is no longer solely employed in analyses of the factors underlying economic growth [and] has proved invaluable, both from the theoretical point of view and in applications... (Nobelprize.org 2013).

Subsequently, Grossman and Helpman (1991) argued that 'almost every product exists on a *quality ladder*, with variants below that may already have become obsolete and others above that have yet to be discovered', and that 'each new product enjoys a limited run at the technological frontier, only to fade when still better products come along'. Harper (2007, p. 103) argued that 'new improved models of high-tech equipment that embody improvements are frequently introduced and marketed alongside older models'.

Substituting (4) into (3),

ln P(death from cancer)
$$\approx \beta$$
 treatment_vintage + ln P(cancer diagnosis) (5)

I will estimate difference-in-difference versions of eq. (5), generalized to include four different types of treatment, using longitudinal, cancer-site-level data on > 60 cancer sites. ^{14,15} The equations will be of the following form:

$$\begin{split} &\ln(\text{mort_rate}_{\text{st}}) = \sum_{k=0}^{4} \left[\beta_{1k} \text{ drug_vintage}_{\text{s,t-k}} + \beta_{2k} \text{ imaging_vintage}_{\text{s,t-k}} \right. \\ &+ \beta_{3k} \text{ radiation_vintage}_{\text{s,t-k}} + \beta_{4k} \text{ surgery_vintage}_{\text{s,t-k}} \\ &+ \gamma_k \ln\left(\text{inc_rate}_{\text{s,t-k}}\right) + \delta_{1k} \text{ age_diag}_{\text{s,t-k}} + \delta_{2k} \text{ \%in_situ}_{\text{s,t-k}} \\ &+ \delta_{3k} \text{ \%loc_reg}_{\text{s,t-k}} + \delta_{4k} \text{ \%distant}_{\text{s,t-k}} + \delta_{5k} \text{ \%male}_{\text{s,t-k}} \\ &+ \delta_{6k} \text{ \%white}_{\text{s,t-k}} \right] + \alpha_{\text{s}} + \delta_{\text{t}} + \varepsilon_{\text{st}} \end{split} \tag{6}$$

Solow assumed that technical progress is embodied in machines because machine manufacturers perform R&D. Because the medical substances and devices industry is much more research-intensive than the machinery industry (National Science Foundation 2013), new medical treatments may embody even more technical progress than new machines.

¹⁴ The cancer sites are those included in the National Cancer Institute's SEER Cause of Death Recode.

Galiani et al. (2005) used a difference-in-differences model to assess the impact of privatization of water services on child mortality in Argentina. They estimated their model using data classified by region and year, whereas the data I will use are classified by disease and year. Their 'treatment variable' (whether water services were publicly or privately provided) was discrete, whereas my treatment variables (vintage indexes) are continuous.

where

```
mort rate<sub>st</sub> = the age-adjusted mortality rate from cancer at site s
                          (s = 1, ..., 60) in year t (t = 1991, ..., 2006)
    drug vintage<sub>s t-k</sub> = index of the vintage of drug procedures associated

                     \alpha_s = a fixed effect for cancer site s
                     \delta_t = a fixed effect for year t
                     \varepsilon_{st} = a disturbance
```

In eq. (6), the cancer mortality rate is postulated to be an unrestricted distributed lag function of the cancer incidence rate and the vintages of the four types of medical procedures in the current year and the four previous years. Eq. (6) includes lagged values of the explanatory variables, as it may take several years for medical innovation to have its peak effect on mortality rates. In this model, the long-run effect of a variable on ln(mort_rate) is the sum of the coefficients on the current and lagged values of the variable, 16 e.g. the long-run effect of drug vintage is $\Sigma_{k=0}^{0}$ β_{1k} A finding that $\Sigma_{k=0}^{4}$ β_{1k} < 0 would signify that cancer sites that had above-average rates of drug innovation (increases in drug vintage) had above-average reductions in the age-adjusted mortality rate, ceteris paribus. The estimation procedure will account for clustering of disturbances within cancer sites.

¹⁶ Wooldridge (2009), p. 344.

Eq. (6) will be estimated via weighted least-squares, weighting by the mean mortality rate of cancer site s during the period 1985–2009. Because the dependent variable is the log of the mortality rate, I am analyzing percentage changes in the mortality rate. As shown in Figure 4, the data exhibit heteroskedasticity: cancer sites with low average mortality rates exhibit much larger positive and negative percentage changes in mortality rates than cancer sites with high average mortality rates. Weighted least-squares is appropriate in the presence of heteroskedasticity.

The four treatment vintage (innovation) measures will all be defined as follows:

$$treatment_vintage_{st} = \frac{\sum_{p} n_proc_{pst} new_{p}}{\sum_{p} n_proc_{pst}}$$
(7)

where

 n_proc_{pst} = the number of times procedure p was performed in connection with cancer diagnosed at site s in year t

 $new_p = 1$ if procedure p is a 'new' procedure

= 0 if procedure p is an 'old' procedure

However, as shown in Table 1, the definition of new_p will vary across treatment categories. Hence, drug_vintage_{st} is defined as the fraction of drug procedures (performed in connection with cancer diagnosed at site s in year t) that utilized drugs approved by the FDA after 1995¹⁷; imaging_vintage_{st} is defined as the fraction of imaging procedures that were advanced procedures; radiation_vintage_{st} is defined as the fraction of radiation procedures that had codes established by the American Medical Association (AMA) after 1995; and surgical_vintage_{st} is defined as the fraction of surgical procedures that had codes established by the AMA after 1995.

I believe that drug_vintage and imaging_vintage are good indicators of the diffusion of drug and imaging innovations, respectively, but I am less confident that radiation_vintage and surgical_vintage are good indicators of the diffusion of radiation and surgical innovations, respectively. Although the AMA (2013) says that establishment of a new Current Procedural Terminology (CPT) code requires that the 'procedure or service [be] clearly identified and distinguished from existing procedures and

150

¹⁷ I performed analyses using alternative measures of drug vintage_{st}, e.g. the fraction of drug procedures that utilized drugs approved by the FDA after 1990 (rather than 1995); this had very little effect on the estimates.

Figure 4 Heteroskedasticity: relationship across cancer sites between average mortality rate and log change in mortality rate.

F. R. Lichtenberg

Table 1 Definition of new procedure indicator (new_p), by treatment category

Treatment category	New _p definition
Drug procedures	= 1 if the active ingredient was approved by the Food and Drug Administration (FDA) after 1995 = 0 otherwise
Imaging procedures	 = 1 if the procedure is designated as an 'advanced imaging' procedure by the Center for Medicare and Medicaid Services (CMS)^a = 0 if the procedure is designated as a 'standard
Radiation procedures	imaging' procedure by CMS = 1 if the CPT code ^b for the procedure was established by the American Medical Association (AMA) after 1995 = 0 otherwise
Surgical procedures	 = 1 if the CPT code for the procedure was established by the American Medical Association after 1995 = 0 otherwise

^a'Advanced imaging' procedures are CAT/CT/CTA (CT angiography) or MRI/MRA (MR angiography) procedures, which are generally newer than 'standard imaging' procedures.

services already in CPT', it seems that in some cases, procedures that are assigned new codes had already been performed under different, existing codes. For example, several psychotherapy procedure codes were retired at the end of 2012, and the procedures were reassigned to new codes. ¹⁸ In the case of radiation and surgical innovations, there may therefore be substantial measurement error in the variable new_p in eq. (7).

The variable new_p is subject to little or no error in the case of drug and imaging innovations, but delays in the establishment by the Center for

152

^bThe Current Procedural Terminology (CPT) code set is maintained by the American Medical Association (AMA) through the CPT Editorial Panel. The CPT code set—copyright protected by the AMA—describes medical, surgical, and diagnostic services and is designed to communicate uniform information about medical services and procedures among physicians, coders, patients, accreditation organizations, and payers for administrative, financial, and analytical purposes.

CPT code 90801 (psychiatric diagnostic interview examination) was replaced by code 90791 (diagnostic evaluation without medical services), and code 90804 (20–30 minutes psychotherapy) was replaced by code 90832 (30 minutes). Source: http://thriveworks.com/blog/2013-cpt-code-revisions-what-the-changes-mean-for-counselors/

Medicare and Medicaid Services or the AMA¹⁹ of codes for new procedures introduce another source of error in eq. (7): n proc_{pst} may be positive but reported as zero during the first few years of a procedure's existence. Consequently, drug vintage is likely to be a 'lagging indicator' of the true diffusion of pharmaceutical innovations. Table 2 shows the FDA approval dates and Healthcare Common Procedure Coding System (HCPCS) code establishment dates for five cancer drugs approved by the FDA in 1996. HCPCS codes for these five drugs were established 19-33 months after FDA approval. These drugs were administered to patients before the establishment of their HCPCS codes. Table 3 shows unpublished IMS Health data for four of these drugs on the number of 'standard units' sold in the USA via retail and hospital channels in the years 1996–1998. According to one Medicare carrier, 'J9999 [not otherwise classified, antineoplastic drugsl is the code that should be used for chemotherapy drugs that do not already have an assigned code'. 20 In all, 16% of chemotherapy treatments for patients with colorectal cancer used code J9999 in 2004.

4 Data sources and descriptive statistics

4.1 Cancer incidence and mortality rates

Data on age-adjusted cancer incidence and mortality rates, by cancer site and year, were obtained from the National Cancer Institute's Cancer Query Systems (http://seer.cancer.gov/canques/index.html). Mortality data are based on a complete census of death certificates and are therefore not subject to sampling error, although they are subject to other errors, i.e. errors in reporting cause of death and age at death. Cancer incidence rates are based on data collected from population-based cancer registries, which currently cover $\sim 26\%$ of the US population; incidence rates are therefore subject to sampling error.

Codes for chemotherapy procedures (and other procedures involving equipment and supplies)—Level II HCPCS codes—are established and maintained by CMS. Codes for other medical services and procedures furnished by physicians and other health care professionals)—CPT codes or Level I HCPCS codes—are established and maintained by the AMA (Center for Medicare and Medicaid Services 2013b).

http://www.palmettogba.com/palmetto/providers.nsf/44197232fa8516898525719600693 9dd/85256d580043e75485256db3004fe953

During the period 1979–1998, cause of death was coded using ICD-9 codes. Since 1999, cause of death has been coded using ICD-10 codes. An advantage of the National Cancer Institute's Cancer Query Systems is that the mortality data from the two periods have been linked together.

Table 2 FDA	approval	dates	and	HCPCS	code	establishment	dates	of	five
cancer drugs a	pproved b	y the	FDA	in 1996

CMS, 2007 Alpha-Numeric HCPCS File, http://www.cms.hhs.gov/HCPCSReleaseCode Sets/downloads/anweb07.zip.

4.2 Medical procedure innovation

Data on the number of medical procedures, by CPT or HCPCS code²², principal diagnosis (International Classification of Diseases-Ninth Revision, ICD-9) code, and year (n_proc_{pst}) were obtained from MEDSTAT MarketScan Commercial Claims and Encounters Database produced by Thomson Medstat (Ann Arbor, MI).²³ Each claim in this database includes information about the procedure performed (CPT code), the patient's diagnosis (ICD-9 code), and the date of service. I extracted data on 1 million outpatient procedures and 1 million inpatient procedures in which the principal diagnosis was cancer in each year during the period 1996–2009.²⁴

The MEDSTAT MarketScan database is not based on a nationally representative sample of Americans. Moreover, the database I use contains data on medical care used by active employees, early retirees,

According to the AMA's CPT Assistant Archives, procedures with CPT codes between 70010 and 75893 are diagnostic imaging procedures.

²³ The MarketScan Databases capture person-specific clinical utilization, expenditures, and enrollment across inpatient, outpatient, prescription drug, and carve-out services from a selection of large employers, health plans, and government and public organizations. The MarketScan Databases link paid claims and encounter data to detailed patient information across sites and types of providers, and over time. The annual medical databases include private sector health data from ∼100 payers. Historically, >500 million claim records are available in the MarketScan Databases. The Commercial Claims and Encounters Database provides data on the medical experience of active employees, early retirees, COBRA continues, and their dependents insured by employer-sponsored plans (i.e., non-Medicare eligibles). I am grateful to the National Bureau of Economic Research for making these data available to me.

More than half of these procedures were diagnostic laboratory and physician attendance procedures.

Table 3 Number of 'standard units' sold in the USA via retail and hospital channels in the years 1996–1998 of four cancer drugs approved by the FDA in 1996

Drug	1996	1997	1998
Docetaxel	36,962	115,191	211,728
Gemcitabine	185,237	508,379	763,405
Topotecan	88,987	150,492	170,665
Irinotecan	117,510	371,832	439,420

Consolidated Omnibus Budget Reconciliation Act (COBRA) continues, and their dependents insured by employer-sponsored plans. Medical care used by people eligible for Medicare is not covered.²⁵ The majority of cancer patients are enrolled in Medicare. Nevertheless, there is likely to be a strong positive correlation across cancer sites between innovations in treatment of non-elderly and elderly patients. If there was more treatment innovation for cancer type A than for cancer type B among non-elderly patients, there was likely to have been more treatment innovation for cancer type A than for cancer type B among elderly patients.

4.3 Measurement of new_n, by treatment category

In the case of drugs, new_p is a dummy variable equal to 1 if the active ingredient was approved by the FDA after 1995, and otherwise equal to 0. To measure new_p for each chemotherapy procedure, I used three databases. The first database, Noridian's NDC to HCPCS Crosswalk, provides a link between (HCPCS) procedure codes and drug product codes (NDCs: National Drug Codes). The second database, the FDA's National Drug Code Directory, provides a link between NDCs and New Drug Application numbers, which are assigned by FDA staff to each application for approval to market a new drug in the USA.²⁶ The third database.

The National Drug Code Directory also includes Abbreviated New Drug Application numbers, which are assigned by FDA staff to each application for approval to market a generic drug in the USA, and Biologic License Application numbers, which are assigned by FDA staff to each application for approval to market biological products under the

provisions of the Public Health Service Act.

I do not have access to a separate MEDSTAT database that covers Medicare-eligible retirees with employer-sponsored Medicare Supplemental plans. The National Cancer Institute publishes data (http://healthservices.cancer.gov/seermedicare/aboutdata/hcpcs. html) on the number of patients in the Patient Entitlement and Diagnosis Summary File (PEDSF) receiving each procedure in each year (1991–2009) by cancer site, but only for four cancer sites (breast, colorectal, lung, and prostate). NCI informed me that, due to budget constraints, it is not able to support the significant amount of programming that would be required to provide similar data for other cancer sites.

the Drugs@FDA database, provides a link between New Drug Application numbers and active ingredients, and allows me to determine the date when each active ingredient was first approved by the FDA.

In the case of imaging procedures, new_p is a dummy variable equal to 1 if the procedure is designated as an 'advanced imaging' procedure by CMS, and otherwise equal to 0. To measure new_p for each imaging procedure, I used CMS' 2013 Berenson-Eggers Type of Service file.

In the case of radiation and surgical procedures, new_p is a dummy variable equal to 1 if the CPT code for the procedure was established by the AMA after 1995, and otherwise equal to 0. To measure new_p for each of these procedures, I used the AMA's CPT Assistant Archives database, which indicates the year in which each CPT code was added, revised, or deleted.

4.4 Other explanatory variables

Data on mean age and cancer stage at time of diagnosis, and on the sex and race of cancer patients, were calculated from the National Cancer Institute's SEER 9 Research Data file (http://seer.cancer.gov/data/). This stage distribution corresponds to 'SEER historic stage A' in the SEER Research Data Record Description: Cases Diagnosed in 1973–2010, http://seer.cancer.gov/data/seerstat/nov2012/TextData.FileDescription.pdf. The SEER 9 Research Data file does not include other measures of socioeconomic status, such as income or educational attainment.

4.5 Descriptive statistics

Data on the number of sample procedures, and on new procedures as a percent of the total number of procedures, by treatment type and year (1996–2009), are shown in Table 4. My sample includes data on about 1.5 million drug procedures, 1.0 million imaging procedures, 1.1 million radiation procedures, and 1.6 million surgical procedures. The fraction of drug procedures that were post-1995 procedures increased from 1% in 1996 to 26% in 2009. The fraction of radiation and imaging procedures that were post-1995 procedures increased by similar amounts: 27 and 23 percentage points, respectively. The large jump between 1999 and 2000 in the fraction of radiation procedures that were post-1995 procedures looks suspicious, however. The fraction of imaging procedures that were advanced procedures increased from 40% in 1996 to 60% in 2009.

Table 5 shows data on mortality, incidence, and treatment in 1996 and 2009, by cancer site, for the top 16 cancer sites (ranked by average mortality rate during 1985–2009).²⁷ It illustrates that the rate of diffusion of

Table A1 shows similar data for the 50 cancer sites not shown in Table 5.

Table 4 Number of sample procedures, and new procedures as percent of total number of procedures, by treatment type and year, 1996–2009

Year	Total drug procedures	Total imaging procedures	Total radiation procedures	Total surgical procedures

medical innovations varied across cancer sites and treatment types. For example, the fraction of drug procedures that were post-1995 procedures increased by almost twice as much for breast cancer (30%) as it did for stomach cancer (16%). But the fraction of imaging procedures that were advanced procedures increased much less for breast cancer (14%) than it did for prostate cancer (37%).

Figure 5 provides data about the 10 drugs with the largest 1996–2009 increase in share of all cancer drug procedures. These 10 drugs accounted for only 2% of drug procedures in 1996, and 25% of procedures in 2009. Seven of the 10 drugs were approved by the FDA after 1995. Figure 6 shows annual data on the fraction of drug procedures that were post-1995 drug procedures for six major cancer sites during 1996–2009.

Figure 7 provides data about the 10 imaging procedures with the largest 1996–2009 increase in share of all cancer imaging procedures. These 10 procedures accounted for 19% of imaging procedures in 1996, and 45% of procedures in 2009. Figure 8 shows annual data on the fraction of imaging procedures that were advanced imaging procedures for six major cancer sites during 1996–2009.

5 Estimates of cancer mortality models

Weighted least-squares estimates of six versions of the model of the age-adjusted mortality rate (eq. (6)) are presented in Table 6. All models include cancer-site fixed effects and year fixed effects, and were estimated using annual data during the period 2000–2009. To conserve space, estimates of cancer-site fixed effects are not reported. Also to conserve space, only estimates of the *sums* of coefficients of current and lagged values of variables (e.g. $\Sigma_{k=0}^{4} \beta_{1k}$) are reported in Table 6.²⁸ As discussed earlier, sums of coefficients are estimates of long-run effects.

Models 1–4, each includes one of the four treatment vintage (innovation) measures. Model 1 includes current and lagged values of drug vintage (post-1995 drug procedures as a percentage of all drug procedures). The sum of the drug vintage coefficients is negative (-0.3807) and highly significant (P = 0.0007), indicating that mortality rates declined more for cancer sites subject to more pharmaceutical innovation, controlling for the change in incidence. The sum of the cancer incidence coefficients is 0.3923 (P < 0.0001): cancer sites with larger declines in incidence had larger declines in mortality. However, the coefficient is much smaller than 1. This is consistent with the view that some changes in measured incidence are due to changes in the probability of diagnosis, as opposed to changes

Estimates of all of the parameters of one model (Model 5) are shown in Table A2.

F. R. Lichtenberg

Figure 5 Ten drugs with the largest 1996–2009 increase in share of all cancer drug procedures.

in true incidence. The sum of the age_diag (mean age at diagnosis) coefficients is positive, as one might expect—earlier diagnosis (lower mean age at diagnosis) is associated with lower mortality—but not significant (P=0.0921). The sums of the coefficients on the stage distribution and %white variables are insignificant.²⁹ The sum of the %male coefficients is positive, as one might expect—men have higher age-adjusted mortality rates—and marginally significant (P=0.0572).

The insignificance of the stage distribution variables is consistent with the 'stage migration' hypothesis (Feinstein et al. 1985). Measured changes in the stage distribution may be due to improvements in diagnostic imaging—metastases that had formerly been silent and unidentified are now identified—rather than a true change in the disease distribution.

Statistically significant estimates (P < 0.05) are bold.

All models were estimated via weighted least-squares, weighting by the mean mortality rate of cancer site s during the period 1985-2009.

Disturbances are clustered within cancer sites. All models include cancer-site fixed effects and year fixed effects (not reported to conserve space), and all models were estimated using annual data during the period 2000-2009.

Also to conserve space, only estimates of the sums of coefficients of current and lagged values of variables (e.g. $\Sigma_{k=0}^4 \beta_{1k}$) are reported. Sums of coefficients are estimates of long-run effects. Model 2 includes current and lagged values of imaging vintage (advanced imaging procedures as a percentage of all imaging procedures). The sum of the imaging vintage coefficients is negative (-0.2438) and significant (P=0.046), indicating that mortality rates also declined more for cancer sites subject to more imaging innovation, controlling for the change in incidence and other included variables.

Model 3 includes current and lagged values of radiation vintage (post-1995 radiation procedures as a percentage of all radiation procedures). The sum of the radiation vintage coefficients is negative (-0.1565) but not significant (P=0.1532). Model 4 includes current and lagged values of surgery vintage (post-1995 surgery procedures as a percentage of all surgery procedures). The sum of the surgery vintage coefficients is also insignificant (P=0.8297). The insignificance of the radiation and surgical innovation measures may be attributable to substantial errors of measurement of radiation and surgical innovation.

Model 5 includes all four treatment vintage (innovation) measures. The coefficients on the measures in this model are not very different from the corresponding coefficients in Models 1–4, suggesting that the four treatment vintage measures are not highly collinear. Model 6 also includes all four treatment vintage (innovation) measures, but excludes current and lagged incidence rates. The sums of the coefficients on the drug and imaging innovation measures are over 50% larger in Model 6 than they are in Model 5: controlling for incidence reduces the estimated effects of drug and imaging innovation. But as eq. (3) indicates that the incidence rate should be included in the mortality rate equation (and also to obtain conservative estimates of the effects of drug and imaging innovation), I will use the estimates of Model 5 to assess the contributions of medical innovation and changes in incidence to the recent decline in cancer mortality.

During the period 2000–2009, the age-adjusted cancer mortality rate declined by 13.8%. If the distribution of cancer deaths by cancer site had not changed, the mortality rate would have declined slightly more, by 14.3%. To calculate the contribution of each factor to the decline in cancer mortality, I multiply the estimated long-run effect of that variable by the long-run change in the variable: the difference between the average value of the variable during 2005–2009 and its average value during 1996–2000. These calculations are shown in Table 7. I calculate the contribution of each factor using the 95% lower and upper bound estimates of long-run effects as well as the mean estimates shown in Table 6 (for Model 5). The mean estimates imply that there were three major sources of decline in the cancer mortality rate. Drug innovation was the largest source: it is estimated to have reduced the cancer mortality rate by 8.0%. Imaging innovation is estimated to have reduced the cancer mortality rate by 4.0%. The 3% decline in the cancer incidence rate is estimated to have reduced the

F. R. Lichtenberg

During the period 2000–2009, the age-adjusted cancer mortality rate declined by 13.8%. If the distribution of cancer deaths by cancer site had not changed, the mortality rate would have declined slightly more, by 14.3%. inc rate_{2005–2009} is the mean value of the age-adjusted incidence rate during 2005–2009.

cancer mortality rate by just 1.2%. Surgical innovation is estimated to have had almost no effect on cancer mortality. The magnitude of the sum of the estimated contributions (13.2%) is only slightly smaller than the observed decline in mortality. Drug and imaging innovation and (to a much lesser extent) declining incidence explain almost the entire decline in cancer mortality.

6 Discussion

Although RCTs undoubtedly provide the most reliable evidence about the impacts of specific treatment innovations (e.g. new drugs or diagnostic procedures) on mortality or survival from a specific type of cancer, it would be exceedingly difficult to assess the overall impact of medical innovation on cancer mortality from a meta-analysis of RCTs. An alternative approach is to perform well-designed econometric analyses of observational data on cancer treatment and outcomes. Several previous econometric studies were subject to several limitations. The outcome measure used in those studies—the cancer survival rate—was potentially subject to lead-time bias. Only one kind of medical innovation—chemotherapy innovation—was usually analyzed, and this was usually measured by the number of drugs potentially available to cancer patients, rather than by the drugs actually used by them.

This article has built on previous research in several ways. The outcome measure used—the *unconditional* cancer mortality rate—is not subject to lead-time bias. I analyzed the effects of four important types of medical innovation—chemotherapy, diagnostic imaging, radiotherapy, and surgical innovation—and cancer incidence rates on cancer mortality rates.

My measures of medical innovation were based on extensive data on treatments given to large numbers of patients with different types of cancer. I allowed there to be a relationship between incidence and mortality, but did not impose a relationship. I also controlled for mean age at diagnosis, the stage distribution of patients at time of diagnosis; and the sex and race of diagnosed patients.

During the period 2000–2009, the age-adjusted cancer mortality rate declined by 13.8%. Under the assumption that there were no pre-dated factors that drove both vintage and mortality, and that there would have been parallel trends in mortality in the absence of innovation, the estimates imply that there were three major sources of decline in the cancer mortality rate. Drug innovation was the largest source: it is estimated to have reduced the cancer mortality rate by 8.0%. Imaging innovation is estimated to have reduced the cancer mortality rate by 4.0%. Estimates of the effects of radiation and surgical innovation were not significant, but these types of innovation are more difficult to measure than drug and imaging innovation. The 3% decline in the cancer incidence rate is estimated to have reduced the cancer mortality rate by just 1.2%. Drug and imaging innovation and (to a much lesser extent) declining incidence explain almost the entire decline in cancer mortality.

Murphy and Topel (2006) estimated that a '1% reduction in cancer mortality would be worth nearly \$500 billion'. This implies that the social value of the reductions in cancer mortality attributable to medical innovations has been enormous, and much greater than the cost of these innovations. For example, the value of the mortality reduction resulting from cancer drug innovation would be \$4.0 trillion (= 8.0 * \$500 billion). Data from IMS Health indicate that total US expenditure on cancer drugs in 2009 was \$40.5 billion; 76% (\$31.0 billion) of this expenditure was on drugs launched after 1995. If Murphy and Topel's and my calculations are correct, the cost of new cancer drugs is less than 1% of the value of the mortality reduction they yielded. This implication is broadly consistent with the findings of Lakdawalla et al. (2010). They found that, between 1988 and 2000, healthcare providers and pharmaceutical companies appropriated 5–19% of the value of gains in cancer survival, with the rest accruing to patients, and that the share of value flowing to patients has been rising over time.
