ABSTRACT

Changes in nominal interest rates must be due to either movements in real interest rates, expected inflation, or the inflation risk premium. We develop a term structure model with regime switches, time-varying prices of risk, and inflation to identify these components of the nominal yield curve. We find that the unconditional real rate curve in the U.S. is fairly flat around 1.3%. In one real rate regime, the real term structure is steeply downward sloping. An inflation risk premium that increases with maturity fully accounts for the generally upward sloping nominal term structure.

1 Introduction

The real interest rate and expected inflation are two key economic variables; yet, their dynamic behavior is essentially unobserved. A large empirical literature has yielded surprisingly few generally accepted stylized facts. For example, whereas theoretical research often assumes that the real interest rate is constant, empirical estimates for the real interest rate process vary between constancy as in Fama (1975), mean-reverting behavior (Hamilton (1985)), or a unit root process (Rose (1988)). There seems to be more consensus on the fact that real rate variation, if it exists at all, should only affect the short end of the term structure but that the variation in long-term interest rates is primarily affected by shocks to expected inflation (see, among others, Mishkin (1990) and Fama (1990)), but this is disputed by Pennacchi (1991). Another phenomenon that has received wide attention is the Mundell (1963) and Tobin (1965) effect: the correlation between real rates and (expected) inflation appears to be negative.

In this article, we seek to establish a comprehensive set of stylized facts regarding real rates, expected inflation and inflation risk premiums, and to determine their relative importance for determining the U.S. nominal term structure. To infer the behavior of these variables, we use a model with three distinguishing features. First, we specify a no-arbitrage term structure model with both nominal bond yields and inflation data to efficiently identify the term structure of real rates and inflation risk premia. Second, our model accommodates regime-switching (RS) behavior, but still produces closed-form solutions for bond prices. We go beyond the extant RS literature by attempting to identify the real and nominal sources of the regime switches. Third, the model accommodates flexible time-varying risk premiums crucial for matching time-varying bond premia (see, for example, Dai and Singleton (2002)). These features allow our model to fit the dynamics of inflation and nominal interest rates.

This paper is organized as follows. Section 2 develops the model and discusses the effect of regime switches on real yields and inflation risk premia. In Section 3, we detail the specification tests used to select the best model, analyze factor dynamics, and report parameter estimates. Section 4 contains the main economic results, which can be summarized as follows:

1. Unconditionally, the term structure of real rates assumes a fairly flat shape around 1.3%, with a slight hump, peaking at a 1-year maturity. However, there are some regimes in which the real rate curve is downward sloping.
2. Real rates are quite variable at short maturities but smooth and persistent at long maturities. There is no significant real term spread.
3. The real short rate is negatively correlated with both expected and unexpected inflation,

but the statistical evidence for a Mundell-Tobin effect is weak.

4. The model matches an unconditional upward-sloping nominal yield curve by generating an inflation risk premium that is increasing in maturity.
5. Nominal interest rates do not behave pro-cyclically across NBER business cycles but our model-implied real rates do.
6. The decompositions of nominal yields into real yields and inflation components at various horizons indicate that variation in inflation compensation (expected inflation and inflation risk premia) explains about 80% of the variation in nominal rates at both short and long maturities.
7. Inflation compensation is the main determinant of nominal interest rate spreads at long horizons.

Finally, Section 5 concludes.

2 A Real and Nominal Term Structure Model with Regime Switches

2.1 Decomposing Nominal Yields

The nominal yield on a zero-coupon bond of maturity n , y_t^n , can be decomposed into a real yield, \hat{y}_t^n , and inflation compensation, $\pi_{t,n}^e$. The real yield represents the yield on a zero-coupon bond perfectly indexed against inflation.¹ Inflation compensation reflects expected inflation, $E_t(\pi_{t+n,n})$, and an inflation risk premium, $\varphi_{t,n}$ (ignoring Jensen's inequality terms):

$$\begin{aligned} y_t^n &= \hat{y}_t^n + \pi_{t,n}^e \\ &= \hat{y}_t^n + E_t(\pi_{t+n,n}) + \varphi_{t,n}, \end{aligned} \tag{1}$$

where $E_t(\pi_{t+n,n})$ is expected inflation from t to $t+n$:

$$E_t(\pi_{t+n,n}) = \frac{1}{n} E_t(\pi_{t+1} + \dots + \pi_{t+n}),$$

¹ Since real interest rates can be defined as real returns on investment, an alternative literature estimates real interest rates by using models of capital and productivity. However, this approach produces very imprecise estimates of real rates with substantial measurement error and often still uses interest rate data to help identification (see Laubach and Williams (2003)).

and π_{t+1} is one-period inflation from t to $t + 1$.

The goal of this article is to achieve this decomposition of nominal yields, y_t^n , into real and inflation components (\hat{y}_t^n , $E_t(\pi_{t+n,n})$, and $\varphi_{t,n}$) for U.S. data. Unfortunately, we do not observe real rates for most of the U.S. sample. Inflation-indexed bonds (the Treasury Income Protection Securities or TIPS) have traded only since 1997 and the market faced considerable liquidity problems in its early days (see Roll (2004)). Consequently, our endeavor faces an obvious identification problem as we must estimate two unknown quantities – real rates and inflation risk premia – from only nominal yields. We obtain identification by using a no-arbitrage term structure model that imposes restrictions on the nominal term structure. That is, the movements of long-term nominal yields are linked both to the dynamics of short-term nominal yields and inflation. These pricing restrictions, together with standard parameter identification restrictions, uniquely identify the dynamics of real rates and inflation risk premiums using data on inflation and nominal yields. To pin down the average level of real rates, we further restrict the one-period inflation risk premium to be zero.

The remainder of this section sets up the model to identify the various components of nominal yields. Section 2.2 presents the technical details of the term structure model, while at the same time discussing the economic background of the term structure factors and our parametric assumptions. The model must be flexible, yet remain identifiable from a finite set of nominal yields. Importantly, both the empirical literature and economic logic suggests that the process generating inflation and real rates may undergo discrete shifts over time, which we model using a RS model following Hamilton (1990). We present solutions to bond prices in Section 2.3 and discuss how regime switches affect our decomposition in Section 2.4. Section 2.5 briefly covers econometric and identification issues. Finally, Section 2.6 discusses how our work relates to the literature.

2.2 The Model

State Variable Dynamics

We employ a three-factor representation of yields, which is the number of factors often used to match term structure dynamics in the finance literature (see, for example, Dai and Singleton (2000)). We incorporate an observed inflation factor, denoted by π_t , which switches regimes. The other two factors are unobservable term structure factors. One factor, f_t , represents a latent RS term structure factor. The other latent factor is denoted by q_t and represents a time-varying, but regime-invariant, price of risk factor, which directly enters into the risk prices (see below). The factor q_t plays two roles. First, it helps generate realistic and plausible time-variation in

expected excess returns on long-term bonds,² as demonstrated by Dai and Singleton (2002). Second, q_t also accounts for part of the time-variation of inflation risk premia, as we show below.

We stack the state variables in the 3×1 vector $X_t = (q_t f_t \pi_t)'$, which follows the RS process:

$$X_{t+1} = \mu(s_{t+1}) + \Phi X_t + \Sigma(s_{t+1})\varepsilon_{t+1}, \quad (2)$$

where s_{t+1} indicates the regime prevailing at time $t + 1$ and

$$\mu(s_t) = \begin{bmatrix} \mu_q \\ \mu_f(s_t) \\ \mu_\pi(s_t) \end{bmatrix}, \quad \Phi = \begin{bmatrix} \Phi_{qq} & 0 & 0 \\ \Phi_{fq} & \Phi_{ff} & 0 \\ \Phi_{\pi q} & \Phi_{\pi f} & \Phi_{\pi\pi} \end{bmatrix}, \quad \Sigma(s_t) = \begin{bmatrix} \sigma_q & 0 & 0 \\ 0 & \sigma_f(s_t) & 0 \\ 0 & 0 & \sigma_\pi(s_t) \end{bmatrix}. \quad (3)$$

The regime variable represents K different regimes, $s_t = 1, \dots, K$, and follows a Markov chain with transition probability matrix $\Pi = \{p_{ij} = Pr(s_{t+1} = j | s_t = i)\}$. These regimes are independent of the shocks ε_{t+1} in equation (2). We specify all the transition probabilities to be constant.³

In equation (3), the conditional mean and volatility of f_t and π_t switch regimes, but the conditional mean and volatility of q_t do not. The feedback parameters for all variables in the companion form Φ also do not switch across regimes. These restrictions are necessary to permit closed-form solutions for bond prices.

We order the factors so that the latent factors appear first. As a consequence, expected inflation depends on lagged inflation, other information captured by the latent variables, as well as a nonlinear drift term. The inflation forecasting literature strongly suggests that expected inflation depends on more than just lagged inflation (see, for example, Stockton and Glassman (1987)). In addition, by placing inflation last in the system, the reduced-form process for inflation involves moving average terms. This is important because the autocorrelogram of inflation is empirically well approximated by a low-order ARMA process.

²Fama and Bliss (1987), Campbell and Shiller (1991), Bekaert, Hodrick and Marshall (1997), and Cochrane and Piazzesi (2005), among many others, document time-variation in expected excess holding period returns of long-term bonds.

³Transition probabilities must be constant under the risk-neutral measure to obtain closed-form solutions for bond prices. A price of RS risk can only be identified if the transition probabilities vary through time. Dai, Singleton and Yang (2006) allow transition probabilities to vary under the real measure, and then define the price of RS risk to perfectly offset the time-varying component of the probability to obtain a constant transition probability under the risk-neutral measure. It is hard to motivate this assumption with an equilibrium model. In contrast, our model can be supported by a representative agent economy with a utility function with habit, and a RS endowment process.

Real Short Rate Dynamics

We specify the real short rate, \hat{r}_t , to be affine in the state variables:

$$\hat{r}_t = \delta_0 + \delta_1' X_t. \quad (4)$$

For reference, we let $\delta_1 = (\delta_q \delta_f \delta_\pi)'$. The real rate process nests the special cases of a constant real rate ($\delta_1 = 0_{3 \times 1}$) advocated by Fama (1975) and mean-reverting real rates within a single regime ($\delta_f = \delta_\pi = 0$) following Hamilton (1985). Allowing non-zero δ_f or δ_π causes the real rate to switch regimes. If $\delta_q \neq 0$, then the time-varying price of risk can directly influence the real rate, as it would in any equilibrium model with growth. In general, if $\delta_\pi \neq 0$, then money neutrality is rejected, and real interest rates are functions of inflation.

The model allows for arbitrary correlation between the real rate and inflation. To gain some intuition, we compute the conditional covariance between real rates and actual or expected inflation for an affine model without regime switches. First, δ_π primarily drives the covariance between real rates and unexpected inflation. That is, $\text{cov}_t(\hat{r}_{t+1}, \pi_{t+1}) = \delta_\pi \sigma_\pi^2$. Second, without regimes, the covariance between expected inflation and real rates is given by:

$$\text{cov}_t(\hat{r}_{t+1}, E_{t+1}(\pi_{t+2})) = \delta_q \Phi_{\pi q} \sigma_q^2 + \delta_f \Phi_{\pi f} \sigma_f^2 + \delta_\pi \Phi_{\pi \pi} \sigma_\pi^2.$$

The Mundell-Tobin effect predicts this covariance to be negative, whereas an activist Taylor (1993) rule would predict it to be positive, as the monetary authority raises real rates in response to high expected inflation (see, for example, Clarida, Galí and Gertler (2000)). Clearly, the sign of the covariance is parameter dependent, and a negative δ_π does not suffice to obtain a Mundell-Tobin effect.

To compare the conditional covariance between real rates and expected inflation in our model with regimes, we derive $\text{cov}_t(\hat{r}_{t+1}, E_{t+1}(\pi_{t+2}) | s_t = i)$ for $K = 2$ regimes to be:

$$\begin{aligned} \text{cov}_t(\hat{r}_{t+1}, E_{t+1}(\pi_{t+2}) | s_t = i) &= \delta_q \Phi_{\pi q} \sigma_q^2 \\ &+ \delta_f \Phi_{\pi f} \left[\sum_{j=1}^2 p_{ij} \sigma_f^2(j) + p_{i1} p_{i2} (\mu_f(1) - \mu_f(2))^2 \right] \\ &+ \delta_\pi \Phi_{\pi \pi} \left[\sum_{j=1}^2 p_{ij} \sigma_\pi^2(j) + p_{i1} p_{i2} (\mu_\pi(1) - \mu_\pi(2))^2 \right] \\ &+ \delta_f \delta_\pi \Phi_{\pi f} \Phi_{\pi \pi} p_{i1} p_{i2} [(\mu_\pi(1) - \mu_\pi(2))(\mu_f(1) - \mu_f(2))]. \end{aligned}$$

Relative to the one-regime model, the contribution of the factor variances for the RS factors now depends on the regime prevailing at time t and has two components: an average of the

two regime-dependent factor variances and a term measuring the volatility impact of a change in the regime-dependent drifts. In addition, there is a new factor contributing to the covariance coming from the covariance between these regime-dependent drifts for f_t and π_t .

Pricing Kernel and Prices of Risk

We specify the real pricing kernel to take the form:

$$\widehat{m}_{t+1} = \log \widehat{M}_{t+1} = -\widehat{r}_t - \frac{1}{2} \lambda_t(s_{t+1})' \lambda_t(s_{t+1}) - \lambda_t(s_{t+1})' \varepsilon_{t+1} \quad (5)$$

where the vector of time-varying and RS prices of risk $\lambda_t(s_{t+1})$ is given by:

$$\lambda_t(s_{t+1}) = (\gamma_t \ \lambda(s_{t+1}))',$$

where $\lambda(s_{t+1})$ is a 2×1 vector of RS prices of risk $\lambda(s_{t+1}) = (\lambda_f(s_{t+1}) \ \lambda_\pi(s_{t+1}))'$ and the scalar γ_t takes the form:

$$\gamma_t = \gamma_0 + \gamma_1 q_t = \gamma_0 + \gamma_1 e_1' X_t, \quad (6)$$

where e_i represents a vector of zeros with a 1 in the i th position. In this formulation, the prices of risk of f_t and π_t change across regimes. The variable q_t controls the time-variation of the price of risk associated with γ_t in equation (6) but does not switch regimes. Allowing γ_t to switch across regimes results in the loss of closed-form solutions for bond prices.

We formulate the nominal pricing kernel in the standard way as $M_{t+1} = \widehat{M}_{t+1} P_t / P_{t+1}$:

$$m_{t+1} = \log M_{t+1} = -\widehat{r}_t - \frac{1}{2} \lambda_t(s_{t+1})' \lambda_t(s_{t+1}) - \lambda_t(s_{t+1})' \varepsilon_{t+1} - e_3' X_{t+1}. \quad (7)$$

Real Factor and Inflation Regimes

We introduce two different regime variables, $s_t^f \in \{1, 2\}$, affecting the drift and variance of the f_t process, and $s_t^\pi \in \{1, 2\}$, affecting the drift and variance of the inflation process. Since both the f_t and π_t factors enter the real short rate in equation (4), the real short rate contains both f_t and π_t regime components. This modeling choice accommodates the possibility that s_t^f captures changes of regimes in real factors. Since f_t enters the conditional mean of inflation in equation (2), the f_t regime also potentially affects expected inflation and can capture nonlinear expected inflation components not directly related to past inflation realizations.

The model with s_t^f and s_t^π can be rewritten using an aggregate regime variable $s_t \in \{1, 2, 3, 4\}$ to account for all possible combinations of $\{s_t^f, s_t^\pi\} = \{(1, 1), (1, 2), (2, 1), (2, 2)\}$. Hence, our model has $K = 4$ regimes. To reduce the number of parameters in the 4×4 transition probability matrix, we consider three restricted models of the correlation between s_t^f and s_t^π .

Case A represents the simplest case of independent regimes. In Cases B and C, the s_t^f and s_t^π regimes are correlated.

In Case B, the current f_t regime depends on the contemporaneous realization of the inflation regime and on the past f_{t-1} regime. Nevertheless, the future inflation regime only depends on current inflation. Case B could represent a reduced-form description of a monetary authority changing real rates, through the latent factor f_t , in response to inflation shocks. We describe this case more fully in Appendix A. However, one shortcoming of Case B is that it cannot capture periods where aggressive real rates, through a regime with high f_t , would successfully stave off a regime of high inflation.

In Case C, the inflation regime at $t + 1$ depends on the stance of the f_{t+1} regime as well as the previous inflation environment, but we restrict future f_{t+1} regimes to depend only on current f_t regimes. This leads to the following conditional transition probability:

$$\begin{aligned}
& Pr(s_{t+1}^f = j, s_{t+1}^\pi = k | s_t^f = m, s_t^\pi = n) \\
&= Pr(s_{t+1}^\pi = k | s_{t+1}^f = j, s_t^f = m, s_t^\pi = n) \times Pr(s_{t+1}^f = j | s_t^f = m, s_t^\pi = n) \\
&= Pr(s_{t+1}^\pi = k | s_{t+1}^f = j, s_t^\pi = n) \times Pr(s_{t+1}^f = j | s_t^f = m), \tag{8}
\end{aligned}$$

where we assume that $Pr(s_{t+1}^\pi | s_{t+1}^f, s_t^f, s_t^\pi) = Pr(s_{t+1}^\pi | s_{t+1}^f, s_t^\pi)$ and $Pr(s_{t+1}^f | s_{t+1}^f, s_t^f) = Pr(s_{t+1}^f | s_t^f)$. We denote $Pr(s_{t+1}^f = 1 | s_t^f = 1) = p^f$ and $Pr(s_{t+1}^f = 2 | s_t^f = 2) = q^f$ and parameterize $Pr(s_{t+1}^\pi = k | s_{t+1}^f = m, s_t^\pi = n)$ as $p^{“j”}, “m”$, where:

$$j = \begin{cases} A & \text{if } s_{t+1}^\pi = s_{t+1}^f = 1 \\ B & \text{if } s_{t+1}^\pi = s_{t+1}^f = 2. \end{cases}$$

The “j”-component captures (potentially positive) correlation between the f_t and π_t regimes. The “m”- component captures persistence in π_t regimes:

$$m = \begin{cases} A & \text{if } s_t^\pi = 1 \\ B & \text{if } s_t^\pi = 2. \end{cases}$$

This formulation can capture instances where a high real rate regime, as captured by the f_t regime, contemporaneously influences the inflation regime. Using the notation introduced above, the transition probability matrix Π for Case C takes the form:

	$[s_{t+1} = 1]$	$[s_{t+1} = 2]$	$[s_{t+1} = 3]$	$[s_{t+1} = 4]$
$[s_t = 1]$	$p^f p^{AA}$	$p^f (1 - p^{AA})$	$(1 - p^f) (1 - p^{BA})$	$(1 - p^f) p^{BA}$
$[s_t = 2]$	$p^f p^{AB}$	$p^f (1 - p^{AB})$	$(1 - p^f) (1 - p^{BB})$	$(1 - p^f) p^{BB}$
$[s_t = 3]$	$(1 - q^f) p^{AA}$	$(1 - q^f) (1 - p^{AA})$	$q^f (1 - p^{BA})$	$q^f p^{BA}$
$[s_t = 4]$	$(1 - q^f) p^{AB}$	$(1 - q^f) (1 - p^{AB})$	$q^f (1 - p^{BB})$	$q^f p^{BB}$

This model has four additional parameters relative to the model with independent real and inflation regimes. We can test Case C against the null of the independent regime Case A by testing the restrictions:

$$H_0 : p^{BA} = 1 - p^{AA} \text{ and } p^{BB} = 1 - p^{AB}.$$

We find evidence to reject the case of independent regimes in favor of Case C with a p-value of 0.033. Thus, our benchmark specification uses the probability transition matrix of Case C.

2.3 Bond Prices

Our model produces closed-form solutions for bond prices, enabling both efficient estimation and the ability to fully characterize real and nominal yields at all maturities without discretization error.

Real Bond Prices

In our model, the real zero coupon bond price of maturity n conditional on regime $s_t = i$, $\widehat{P}_t^n(s_t = i)$, is given by:

$$\widehat{P}_t^n(i) = \exp(\widehat{A}_n(i) + \widehat{B}_n X_t), \quad (9)$$

where $\widehat{A}_n(i)$ is dependent on regime $s_t = i$, \widehat{B}_n is a $1 \times N$ vector and N is the total number of factors in the model, including inflation. The expressions for $\widehat{A}_n(i)$ and \widehat{B}_n are given in Appendix B. Since the real bond prices are given by (9), it follows that the real yields $\widehat{y}_t^n(i)$ conditional on regime i are affine functions of X_t :⁴

$$\widehat{y}_t^n(i) = -\frac{\log(\widehat{P}_t^n)}{n} = -\frac{1}{n}(\widehat{A}_n(i) + \widehat{B}_n X_t). \quad (10)$$

While the expressions for $\widehat{A}_n(i)$ and \widehat{B}_n are complex, some intuition can be gained on how the prices of risk affect each term. The prices of risk γ_0 and $\lambda(s_t)$ enter only the constant term in the yields $\widehat{A}_n(s_t)$, but affect this term in all regimes. More negative values of γ_0 or $\lambda(s_t)$ cause long maturity yields to be, on average, higher than short maturity yields. In addition, since the $\lambda(s_t)$ terms differ across regimes, $\lambda(s_t)$ also controls the regime-dependent level of the yield curve away from the unconditional shape of the yield curve. Thus, the model can accommodate the switching signs of term premiums documented by Boudoukh et al. (1999). The prices of

⁴ The technical innovation in deriving (9) is to recognize that the \widehat{B}_n parameter does not switch for two reasons. First, Φ remains constant across regimes. Second, the time-varying price of risk parameter γ_1 also does not switch across regimes. If these parameters become regime dependent, closed-form bond solutions are no longer possible.

risk affect the time-variation in the yields through the parameter γ_1 . This term only enters the \widehat{B}_n terms. A more negative γ_1 means that long-term yields respond more to shocks in the price of risk factor q_t .

The pricing implications of (10), together with the assumed dynamics of X_t in (2), imply that the autoregressive dynamics of inflation and bond yields are constant over time, but the drifts vary through time, and shocks to inflation and real yields are heteroskedastic. Hence, our model is consistent with the macro models of Sims (1999, 2001) and Bernanke and Mihov (1998), who stress changing drifts, for example induced by changes in monetary policy, and heteroskedastic shocks. On the other hand, Cogley and Sargent (2001, 2005) advocate models with changes in the feedback parameters, for example induced by changes in systematic monetary policy, which we do not accommodate.

Nominal Bond Prices

Nominal bond prices take the form:

$$P_t^n(i) = \exp(A_n(i) + B_n X_t) \quad (11)$$

for $P_t^n(i)$, the zero-coupon bond price of a nominal n -period bond conditional on regime i . The scalar $A_n(i)$ is dependent on regime $s_t = i$ and B_n is an $1 \times N$ vector. It follows that the nominal n -period yield conditional on regime i , $y_t^n(i)$, is an affine function of X_t :

$$y_t^n(i) = -\frac{\log(P_t^n)}{n} = -\frac{1}{n}(A_n(i) + B_n X_t). \quad (12)$$

Appendix C shows that the only difference between the $\widehat{A}_n(i)$ and \widehat{B}_n terms for real bond prices and the $A_n(i)$ and B_n terms for nominal bond prices are due to terms that select inflation from X_t . Positive inflation shocks decrease nominal bond prices.

2.4 The Effect of Regime Switches

The key ingredient differentiating our model from the standard affine term structure paradigm is the presence of regimes. In this section, we develop intuition on how regimes affect the decomposition of nominal rates into real rate and inflation components.

Expected Inflation

In our model, one-period expected inflation, $E_t(\pi_{t+1})$, takes the form:

$$\begin{aligned} E_t(\pi_{t+1}|s_t = i) &= e_3' E[\mu(s_{t+1})|s_t = i] + e_3' \Phi X_t \\ &= \left(\sum_{j=1}^K p_{ij} \mu_\pi(j) \right) + e_3' \Phi X_t. \end{aligned} \quad (13)$$

This process is only different from a simple linear process because of the nonlinear drift, which can accommodate sudden discrete changes in expected inflation. Because expected inflation depends on f_t and π_t , the contemporaneous s_t^f and s_t^π regimes also both affect expected inflation.

Inflation Compensation

With only one regime, one-period inflation compensation, $\pi_{t,1}^e = y_t^1 - \hat{r}_t$, is given by:

$$\pi_{t,1}^e = \left(\mu_\pi - \frac{1}{2} \sigma_\pi^2 - \sigma_\pi \lambda_\pi \right) + e_3' \Phi X_t.$$

With regimes, inflation compensation is more complex:

$$\pi_{t,1}^e(i) = -\log \left[\sum_{j=1}^K p_{ij} \exp \left(-\mu_\pi(j) + \frac{1}{2} \sigma_\pi^2(j) + \sigma_\pi(j) \lambda_\pi(j) \right) \right] + e_3' \Phi X_t, \quad (14)$$

The last term in the exponential represents the one-period inflation risk premium, which is zero by assumption in our model. The $\frac{1}{2} \sigma_\pi^2(j)$ term is the standard Jensen's inequality term, which now becomes regime dependent. The $-\mu_\pi(s_t)$ term represents the nonlinear, regime-dependent part of expected inflation. The last term $e_3' \Phi X_t$ represents the time-varying part of expected inflation, which does not switch across regimes, and is the only term that is the same as in the affine model.

In comparing expected inflation in equation (13) with inflation compensation in equation (14), we see that the constant terms for $\pi_{t,1}^e$ and $E_t(\pi_{t+1}|s_t)$ are different. The constants in the inflation compensation expression (14) reflect both a Jensen's inequality term $\frac{1}{2} \sigma_\pi^2(s_t)$ and a nonlinear term, driven by taking the log of a sum, weighted by transition probabilities. Because $\exp(\cdot)$ is a convex function, Veronesi and Yared (1999) call this effect a ‘‘convexity bias.’’ Like the Jensen's term, this also makes $\pi_{t,1}^e < E_t(\pi_{t+1})$. In our estimations, both the Jensen's term and the convexity bias amount to less than 1 basis point, even for longer maturities.

Real Term Spreads

The intuition for how regimes affect real term spreads can be readily gleaned from considering a two-period real bond. We first analyze the case of the real term spread, $\hat{y}_t^2 - \hat{r}_t$, in an affine model without regime switches:

$$\hat{y}_t^2 - \hat{r}_t = \frac{1}{2} (E_t(\hat{r}_{t+1}) - \hat{r}_t) - \frac{1}{4} \text{var}_t(\hat{r}_{t+1}) + \frac{1}{2} \text{cov}_t(\hat{m}_{t+1}, \hat{r}_{t+1}). \quad (15)$$

The first term $(E_t(\hat{r}_{t+1}) - \hat{r}_t)$ is an Expectations Hypothesis (EH) term, the second term $\text{var}_t(\hat{r}_{t+1})$ is a Jensen's inequality term and the last term, $\text{cov}_t(\hat{m}_{t+1}, \hat{r}_{t+1})$, is the risk premium.

In the single-regime affine setting, the last term is given by:

$$\text{cov}_t(\widehat{m}_{t+1}, \widehat{r}_{t+1}) = -\gamma_0\sigma_q - \lambda_f\sigma_f - \gamma_1\sigma_q q_t. \quad (16)$$

Hence, the price of risk factor q_t determines the time variation in the term premium.

The RS model has a more complex expression for the two-period real term spread:

$$\begin{aligned} \widehat{y}_t^2(i) - \widehat{r}_t = & \frac{1}{2}(\mathbb{E}_t(\widehat{r}_{t+1}|s_t = i) - \widehat{r}_t) - \frac{1}{2}(\gamma_0\sigma_q + \gamma_1\sigma_q q_t) \\ & - \frac{1}{2} \log \left(\sum_{j=1}^K p_{ij} \exp \left[-\delta'_1 \left(\mu(j) - \mathbb{E}[\mu(s_{t+1})|s_t = i] \right) \right. \right. \\ & \left. \left. + \frac{1}{2} \delta'_1 \Sigma(j) \Sigma(j)' \delta_1 + \lambda_f(j) \sigma_f(j) \right] \right), \quad (17) \end{aligned}$$

for K regimes. First, the term spread now switches across regimes, explicitly shown by the dependence of $\widehat{y}_t^2(i)$ on regime $s_t = i$. Not surprisingly, the EH term $(\mathbb{E}_t(\widehat{r}_{t+1}|s_t = i) - \widehat{r}_t)$ now switches across regimes. The time-varying price of risk term, $-\frac{1}{2}(\gamma_0\sigma_q + \gamma_1\sigma_q q_t)$, is the same as in (16) because the process for q_t does not switch regimes. The remaining terms in (17) are nonlinear, as they involve the log of the sum of an exponential function of regime-dependent terms, weighted by transition probabilities. Within the nonlinear expression, the term $\frac{1}{2} \delta'_1 \Sigma(j) \Sigma(j)' \delta_1$ represents a Jensen's inequality term, which is regime-dependent, and $\lambda_f(j) \sigma_f(j)$ represents a RS price of risk term. Thus, the average slope of the real yield curve can potentially change across regimes and produce a variety of regime-dependent shapes of the real yield curve, including flat, inverse-humped, upward-sloping or downward-sloping yield curves. A new term in (17) that does not have a counterpart in (16) is $-\delta'_1(\mu(j) - \mathbb{E}[\mu(s_{t+1})|s_t = i])$, reflecting the ‘‘jump risk’’ of a change in the regime-dependent drift.

Inflation Risk Premia

The riskiness of nominal bonds is driven by the covariance between the real kernel and inflation: if inflation is high (purchasing power is low) when the pricing kernel realization (marginal utility in an equilibrium model) is high, nominal bonds are risky and the inflation risk premium is positive. It is tempting to conclude that the sign of the inflation risk premium determines the correlation between expected inflation and real rates. For example, a Mundell-Tobin effect implies that when a bad shock is experienced (an increase in real rates), the holders of nominal bonds experience a countervailing effect, namely a decrease in expected inflation, which increases nominal bond prices. This intuition is not completely correct as we now discuss.

Consider the two-period pricing kernel, which depends on real rates both through its conditional mean and through real rate innovations. Interestingly, the effects of these two

components are likely to act in opposite directions. High real rates decrease the conditional mean of the pricing kernel; but, if the price of risk is negative, positive shocks to the real rate should increase marginal utility. We first focus on the affine model. By splitting inflation into unexpected and expected inflation, we can decompose the two-period inflation risk premium, $\varphi_{t,2}$, into four components (ignoring the Jensen's inequality term):

$$\begin{aligned} \varphi_{t,2} = \frac{1}{2} [& -\text{cov}_t(\hat{r}_{t+1}, E_{t+1}(\pi_{t+2})) - \text{cov}_t(\hat{r}_{t+1}, \pi_{t+1}) \\ & + \text{cov}_t(\hat{m}_{t+1}, E_{t+1}(\pi_{t+2})) + \text{cov}_t(\hat{m}_{t+1}, \pi_{t+1})] \quad (18) \end{aligned}$$

The first two terms reveal that a negative correlation between real rates and both expected and unexpected inflation actually implies a positive risk premium. Nevertheless, a Mundell-Tobin effect does not necessarily imply a positive inflation risk premium because of the last two terms, which involve the innovations of the pricing kernel. In the affine model equivalent of our RS model, the last term is zero by assumption, but the third term is not and may swamp the others. In particular, for the affine specification:

$$\varphi_{t,2} = -\frac{1}{2} [\delta_\pi \sigma_\pi^2 (1 + \Phi_{\pi\pi}) + \Phi_{\pi q} (\sigma_q^2 + \gamma_1 \sigma_q q_t) + \Phi_{\pi f} (\sigma_f^2 + \lambda_f \sigma_f)]. \quad (19)$$

Hence, the time-variation in the inflation risk premium depends on q_t , and the mean premium depends on parameters that also determine the correlation between real rates and inflation. In particular, if the correlation between real rates and inflation is zero (requiring $\delta_\pi = \Phi_{\pi,q} = \Phi_{\pi,f} = 0$), then the inflation risk premium is also zero. Note that the price of risk λ_f plays a role in determining the inflation risk premium whereas it does not play a role in determining the correlation between real rates and expected inflation.

Naturally, the RS model has a richer expression for the inflation risk premium than equation (19). Conditional on $s_t = i$, the two-period inflation risk premium in our model is given by:

$$\begin{aligned} \varphi_{t,2}(i) = & -\frac{1}{2} \left\{ \sum_{j=1}^K p_{ij} \left[\left(\mu_f(j) + \delta_\pi \mu_\pi(j) + \frac{1}{2} \lambda_f^2(j) \right) \times \right. \right. \\ & \left. \left. \left((1 + \Phi_{\pi\pi}) \mu_\pi(j) + \sum_{k=1}^K p_{jk} \mu_\pi(k) + \Phi_{\pi f} \mu_f(j) \right) \right] \right. \\ & - \left. \left[\sum_{j=1}^K p_{ij} \left(\mu_f(j) + \delta_\pi \mu_\pi(j) + \frac{1}{2} \lambda_f^2(j) \right) \right] \times \right. \\ & \left. \left[\sum_{j=1}^K p_{ij} \left((1 + \Phi_{\pi\pi}) \mu_\pi(j) + \sum_{k=1}^K p_{jk} \mu_\pi(k) + \Phi_{\pi f} \mu_f(j) \right) \right] \right\} \end{aligned}$$

$$\begin{aligned}
& + \delta_\pi (1 + \Phi_{\pi\pi}) \sum_{j=1}^K p_{ij} \sigma_\pi^2(j) + \Phi_{\pi q} (\sigma_q^2 + \gamma_1 \sigma_q q_t) \\
& + \Phi_{\pi f} \sum_{j=1}^K p_{ij} \left(\sigma_f^2(j) + \lambda_f(j) \sigma_f(j) \right) \Big\} \tag{20}
\end{aligned}$$

The time-varying inflation risk term involving q_t is the same as the affine model, but the other terms become regime dependent and nonlinear. The inflation risk premium is affected by regime switches both through the RS price of risk, $\lambda_f(s_{t+1})$, and also through the regime-dependent means.⁵ The effects of the RS drifts impart considerable flexibility to introduce nonlinear movements in the risk premium, especially the ability to induce sudden shifts due to changing inflation environments.

2.5 Econometrics and Identification

We derive the likelihood function of the model in Appendix D. The likelihood is not simply the likelihood of the yields measured without error multiplied by the likelihood of the measurement errors, which would be the case in a standard affine model estimation. Instead, the regime variables must be integrated out of the likelihood function. Our model implies a RS-VAR for inflation and yields with complex cross-equation restrictions imposed by the term structure model.

Since the model has latent factors, identification restrictions must be imposed to estimate the model. We also discuss these issues in Appendix D. An important identification assumption is that we set the one-period inflation risk premium equal to zero, $\lambda_\pi(s_{t+1}) = 0$. This parameter identifies the average level of real rates and the inflation risk premium, and is very hard to identify without using real yields in the estimation. This restriction does not undermine the ability of the model to fit the dynamics of nominal interest rates and inflation well, as we show below. Models with non-zero λ_π give rise to lower and more implausible real rates than our estimates imply and have a poorer fit with the data.

Finally, we specify the dependence of the prices of risk for the f_t and π_t factors on s_t . Because we set $\lambda_\pi = 0$, we only need to model $\lambda_f(s_{t+1})$. In general, there are four possible λ_f parameters across the four s_{t+1} regimes. This potentially allows real and nominal yield curves to take on different unconditional shapes in different inflationary environments. When

⁵ In particular, in the RS model, the term $\text{cov}_t(\hat{m}_{t+1}, \pi_{t+1})$ is not zero even though we assume $\lambda_\pi = 0$, but this term is less than 1 basis point in our estimation.

estimating a model where $\lambda(s_{t+1})$ varies over all regimes, a Wald test on the equality of $\lambda(s_{t+1})$ across s_{t+1}^π regimes is strongly rejected with a p-value less than 0.001, while a Wald test on the equality of $\lambda(s_{t+1})$ across s_{t+1}^f regimes is not rejected at the 5% level. Hence, in our benchmark model, we consider prices of f risk to vary only across inflation regimes, s_{t+1}^π .

2.6 Related Models

To better appreciate the relative contribution of the model, we link it to three distinct literatures: (i) the extraction of real rates and expected inflation from nominal yields and realized inflation or inflation forecasts, (ii) the empirical RS literature on interest rates and inflation, and (iii) the theoretical term structure literature and equilibrium affine models in finance.

Time-Series Models

An earlier literature uses neither term structure data, nor a pricing kernel to obtain estimates of real rates and expected inflation. Mishkin (1981) and Huizinga and Mishkin (1986) simply project ex-post real rates on instrumental variables. This approach is sensitive to measurement error and omitted variable bias. Other authors, such as Hamilton (1985), Fama and Gibbons (1982), and Burmeister, Wall and Hamilton (1986), use low-order ARIMA models and identify expected inflation and real rates using a Kalman filter, under the assumption of rational expectations. The time-series processes driving real rates and expected inflation, with rational expectations, remain critical ingredients in our approach, but we use inflation data and the entire term structure to obtain more efficient identification. In addition, our approach identifies the inflation risk premium, which this literature cannot do.

Empirical Regime-Switching Models

Many articles document RS behavior in interest rates (see, among many others, Hamilton (1988), Gray (1996) Sola and Driffill (1994), Bekaert, Hodrick and Marshall (2001), and Ang and Bekaert (2002a)) without analyzing the real and nominal sources of the regimes. Evans and Wachtel (1993) and Evans and Lewis (1995) document the existence of inflation regimes, whereas Garcia and Perron (1996) focus on real interest rate regimes. Our model simultaneously identifies inflation and real factor sources behind the regime switches and analyzes how they contribute to nominal interest rate variation.

Term Structure Models

Relative to the extensive term structure literature, our model appears to be the first to identify

real interest rates and the components of inflation compensation in a model accommodating regime switches, while still admitting closed-form solutions. Most of the articles using a pricing model to obtain estimates of real rates and expected inflation have so far ignored RS behavior. This includes papers by Pennacchi (1991), Boudoukh (1993) and Buraschi and Jiltsov (2005) for U.S. data and Barr and Campbell (1997) and Evans (1998) for U.K. data. This is curious, because the early literature implicitly demonstrated the importance of accounting for potential structural or regime changes. For example, the Huizinga-Mishkin (1986) projections are unstable over the 1979-1982 period, and the slope coefficients of regressions of future inflation onto term spreads in Mishkin (1990) are substantially different pre- and post-1979, which is also recently confirmed by Goto and Torous (2003).

The articles that have formulated term structure models accommodating regime switches mostly focus only on the nominal term structure. Articles by Hamilton (1998), Bekaert, Hodrick and Marshall (2001), Bansal and Zhou (2002), and Bansal, Tauchen and Zhou (2004) allow for RS in mean reversion parameters which we do not, but their derived bond pricing solutions, using discretization or linearization, are only approximate. None of these models features a time-varying price of risk factor like q_t in our model. Naik and Lee (1994) and Landén (2000) present models with closed-form bond prices, but these models feature constant prices of risk and only shift the constant terms in the conditional mean.

The RS term structure model by Dai, Singleton and Yang (2006) incorporates regime-dependent mean reversions and state-dependent probabilities under the real measure, while still admitting closed-form bond prices. However, under the risk-neutral measure, both the mean reversion and the transition probabilities must be constants, exactly as in our formulation. Dai, Singleton and Yang allow for only two regimes, while we have a much richer RS specification. Another point of departure is that in their model, the evolution of the factors and the prices of risk depend on s_t rather than s_{t+1} . In contrast, our model specifies regime dependence using s_{t+1} as in Hamilton (1989), implying that the conditional variances of our factors embed a jump term reflecting the difference in conditional means across regimes. This conditional heteroskedasticity is absent in the Dai-Singleton-Yang parameterization. Our results show that the conditional means of inflation significantly differ across regimes, while the conditional variances do not, making the regime-dependent means an important source of inflation heteroskedasticity.

There are two related articles that use a term structure model with regime switches to investigate real and nominal yields. The first specification by Veronesi and Yared (1999) is quite restrictive as it only accommodates switches in the drifts. The second paper by Evans (2003) is most closely related to our article. He formulates a model with regime switches for

U.K. real and nominal yields and inflation, but he does not accommodate time-varying prices of risk. Evans incorporates switches in mean-reversion parameters, but does not separate the sources of the regime switches into real factors and inflation.⁶

Final Comments

While the model is quite general, it has two main caveats. First, Gray (1996) and Bekaert, Hodrick and Marshall (2001), among others, show that mean-reversion of the short rate is significantly different across regimes. Evans and Wachtel (1993) and Evans and Lewis (1995) also present some evidence for state-dependent mean reversion in inflation. Second, Ang and Bekaert (2002b) show that only time-varying transition probabilities can reproduce the nonlinearities in the short rate drift and volatility functions documented by Ait-Sahalia (1996) and others. If we relax either of these constraints, we can no longer derive closed-form bond prices. While these are important concerns, the numerical difficulties in computing bond prices for these more complex specifications are formidable and the use of term structure information is critical in identifying both the inflation and real rate components in nominal interest rates. Moreover, our model with a latent term structure factor and a time-varying price of risk, combined with the RS means and variances, is very rich and cannot be identified from inflation and short rate data alone. Despite these two caveats, we show below that our model provides a good fit with the data in terms of matching data moments.

3 Model Estimates

3.1 Data

We use 4-, 12- and 20-quarter maturity zero-coupon yield data from CRSP and the 1-quarter rate from the CRSP Fama risk-free rate file as our yield data. We compute inflation from the Consumer Price Index – All Urban Consumers (CPI-U, seasonally adjusted, 1982:Q4=100), from the Bureau of Labor Statistics. Our data spans the sample from 1952:Q2 to 2004:Q4. Using monthly CPI figures creates a timing problem because prices are collected over the course

⁶ Evans (2003) claims to derive an exact, closed-form bond pricing formula that switches in the mean-reversion term, but his claim is erroneous. On p378 of his article, Evans defines $\Phi_{k,t}^j$ to be a vector that does not depend on the regime s_t , but this should be a matrix $\Phi_{k,t}^j(\tilde{s}, s)$, representing values for all transitions between s_t and s_{t+1} . Dai and Singleton (2003) show that when Φ becomes state-dependent, the bond prices are given by a solution to a series of coupled partial differential equations. This reduces to our differential equation solutions (see below) only for the case when Φ is not regime dependent. When Φ is regime dependent under the risk-neutral measure, closed-form solutions can no longer be obtained.

of the month and monthly inflation data is seasonal. Therefore, similar to Campbell and Viceira (2001), we sample all data at the quarterly frequency. For the benchmark model, we specify the 1-quarter and 20-quarter yields to be measured without error to extract the unobserved factors (see Chen and Scott (1993)). The other yields are specified to be measured with error and provide over-identifying restrictions for the term structure model.⁷

3.2 Model Nomenclature

In Table 1, we describe the different term structure models we estimate. The top row represents models with the three factors $(q_t \ f_t \ \pi_t)'$. In the bottom row, we list alternative models that add an unobserved factor representing expected inflation, which we denote by w_t , which generalize classic ARMA-models of expected inflation. We describe these models in Appendix E.

To gauge the contribution of regime switches, we estimate single-regime counterparts to the benchmark and unobserved expected inflation models. The single regime models I and I_w are simply affine models. Model I is the single regime counterpart of the benchmark RS model IV , described in Section 2. Model I_w is similar to the model estimated by Campbell and Viceira (2001), except that Campbell and Viceira assume that the inflation risk premium is constant, whereas in all our models the inflation risk premium is stochastic. We specifically contrast real rates and inflation risk premia from Model I_w with the real rates and inflation risk premia implied by our benchmark model below.

The remaining models in Table 1 are RS models. Models II and II_w contain two regimes where $s_t^f = s_t^\pi$. Two regime models are the main specifications used in the empirical and term structure literature (see, for example, Bansal and Zhou (2002)). Model III considers a similar model but the regime variable can take on three values. Model IV represents the benchmark model, which has four regimes, with the different cases describing the correlation of the s_t^f and the s_t^π regimes (Cases A, B, and C as described in Section 2.2). Model VI contains two regimes for s_t^f which are independent of the three regimes for s_t^π .

3.3 Specification Tests

We report two specification tests of the models, an unconditional moment test and an in-sample serial correlation test for first and second moments in scaled residuals. The former is particularly important because we want to decompose the variation of nominal yields into real and expected

⁷ We estimate several of our models using alternative schemes where other yields are assumed to be measured without error and find that the results are very similar.

inflation components. A well-specified model should imply unconditional means, variances and autocorrelograms of inflation and yields close to the sample moments. We outline these tests in Appendix F.

Table 2 reports the results of these specification tests. Panel A focuses on matching inflation dynamics, while Panel B focuses on matching the dynamics of yields. Of all the models, only Model IV^C passes the inflation residual tests and fits the mean, variance, and autocorrelogram of inflation (using autocorrelations of lags 1, 5, and 10). About half of the models fail to match the autocorrelogram of inflation. Inflation features a relatively low first-order autocorrelation coefficient with very slowly decaying higher-order autocorrelations. Generally, the presence of regimes and the additional expected inflation factor help in matching this pattern. However, most of the models with the w -factor fail to match the mean and variance of inflation. While Model VI passes all moment tests, both residual tests reject strongly at the 1% level, eliminating this model. The match with inflation dynamics is extremely important as the estimated inflation process not only identifies expected inflation but also plays a critical role in identifying the inflation risk premium. This makes Model IV^C the prime candidate for the best model.

Panel B reports goodness-of-fit tests for two sets of yield moments: the mean and variance of the spread and the long rate (all models fit the mean of the short rate by construction in the estimation procedure) and the autocorrelogram of the spread. Only four models fit the moments of yields and spreads: I , III , IV^A , and IV^C . Unfortunately, apart from model IV^C , these other models fail to match the inflation moments in Panel A.

We also report the residual test for the short rate and spread equations in Panel B. With the exception of models IV^B and VI , most models produce reasonably well-behaved residuals. While model IV^C nails the dynamics of inflation in Panel A and closely matches term structure moments, the model's residual tests for short rates and spreads are significant at the 5% level, but not at the 1% level. Thus, there is some serial correlation and heteroskedasticity that remains present in the residuals. Consequently, the unconditional moments of unobserved real rates and inflation risk premia produced by model IV^C will imply nominal rates and inflation behavior close to that in data, but the conditional dynamics of real short rates and inflation risk premia may be slightly more persistent or heteroskedastic than our estimates suggest.

3.4 Model Estimates

We focus on the benchmark model IV^C , which is the model that best fits the inflation and term structure data.⁸ We discuss the parameter estimates, the implied factor dynamics, and the

⁸ Estimates of other models are available upon request.

identification and interpretation of the regimes.

Parameter Estimates

Table 3 reports the parameter estimates. Inflation enters the real short rate equation (4) with a highly significant, negative coefficient of $\delta_\pi = -0.49$. In the companion form Φ of the VAR, the term structure latent factors q_t and f_t are both persistent, with correlations of 0.97 and 0.76, respectively. Their effects on the conditional mean of inflation and thus on expected inflation is positive with coefficients of 0.62 and 0.95, respectively. However, the coefficient on f_t is only borderline significant with a t-statistic of 1.85. Not surprisingly, lagged inflation also significantly enters the conditional mean of inflation, with a loading of 0.54. A test of money neutrality ($\delta_\pi = \Phi_{\pi,q} = \Phi_{\pi,f} = 0$) rejects with a p-value less than 0.001.

The conditional means and variances of the factors reveal that the first $s_t^f = 1$ regime is characterized by a low f_t mean and low standard deviation. Both the mean and standard deviations are significantly different across the two regimes at the 5% level. For the inflation process, the conditional mean of inflation is significantly different across the s_t^π regimes, with $s_t^\pi = 1$ being a relatively high inflation environment. However, there is no significant difference across regimes in the innovation variances. This does not mean that inflation is homoskedastic in this model. The regime-dependent means of f_t induce heteroskedastic inflation across the f_t factor regimes.

Table 3 also reports that the price of risk for the q_t factor is negative but imprecisely estimated. The prices of risk for the f_t factor are both significantly different from zero and significantly different across the two regimes. Moreover, they have a different sign in each regime, which may induce different term structure slopes across the regimes.

The transition probability matrix shows that the s_t^f regimes are persistent with probabilities $Pr(s_{t+1}^f = 1 | s_t^f = 1) = 0.93$ and $Pr(s_{t+1}^f = 2 | s_t^f = 2) = 0.77$. The probability $p^{AA} = Pr(s_{t+1}^\pi = 1 | s_{t+1}^f = 1, s_t^\pi = 1)$ is estimated to be one. Conditional on a period with a negative f_t and relatively high inflation (regime 1), we cannot transition into a period of lower expected inflation unless the f_t regime also shifts to the higher mean regime. Thus, the model assigns zero probability from transitioning from $s_t = 1 \equiv (s_t^f = 1, s_t^\pi = 1)$ to $s_{t+1} = 2 \equiv (s_{t+1}^f = 1, s_{t+1}^\pi = 2)$. Similarly, starting in regime 3, $s_t = 3 \equiv (s_t^f = 2, s_t^\pi = 1)$, we can transition into the low inflation regime ($s_{t+1}^\pi = 2$) only with a realization of $s_{t+1}^f = 2$, where f_t is high and volatile. We demonstrate below that this behavior has a plausible economic interpretation.

Factor Behavior

Table 4 reports the relative contributions of the different factors driving the short rate, long

yield, term spread, and inflation dynamics in the model. The price of risk factor q_t is relatively highly correlated with both inflation and the nominal short rate, but shows little correlation with the nominal spread. In other words, q_t can be interpreted as a level factor. The RS term structure factor f_t is highly correlated with the nominal spread, in absolute value, so f_t is a slope factor. The factor f_t is also less variable and less persistent than q_t . Consequently, f_t does not play a large role in the dynamics of the real rate, only accounting for 9% of its variation. The most variable factor is inflation and it accounts for 51% of the variation of the real rate. Inflation is negatively correlated with the real short rate, at -34%, as a result of the negative $\delta_\pi = -0.49$ coefficient, while q_t is positively correlated with the real short rate (44%). The model produces a 69% (-44%) correlation between inflation and the nominal short rate (nominal 5-year spread), which matches the data correlation of 68% (-37%) very closely.

Panel A also reports how the different factors contribute to the expected inflation dynamics. The latent factor components play an important role in the dynamics of expected inflation, with q_t and f_t accounting for 37% of the variance of expected inflation. Inflation itself accounts for 62% of the variance of inflation. Expected inflation also has a nonlinear RS component. We calculate the contribution of regimes to the variance of expected inflation by computing the variance of expected inflation assuming we never transition from regime 1, relative to the variance of expected inflation from the full model. Unconditionally, RS accounts for 12% of the variance of expected inflation. We also show later that regimes are critical for capturing sudden decreases in expected inflation occurring occasionally during the sample.

The implied processes for expected inflation and actual inflation are both very persistent. The first-order autocorrelation coefficient of one-quarter expected inflation is 0.89, which implies a monthly autocorrelation coefficient of 0.96 under the null of an AR(1). The autocorrelations decay slowly to 0.51 at 10 quarters. Fama and Schwert (1977) also note the strong persistence of expected inflation using time-series techniques to extract expected inflation estimates. For actual inflation, the first-order autocorrelation implied by the model is 0.76 and it is 0.35 at 10 quarters, matching the data almost perfectly at 0.72 and 0.35, respectively.⁹ It is this very persistent nature of inflation that many of the other models cannot match. For example, in model I_w similar to Campbell and Viceira (2001), the autocorrelations of actual inflation are 0.48 and 0.20 at one and 10 lags, respectively.

Because the factors are highly correlated with inflation, the nominal short rate and the nominal spread, these three variables should capture a substantial proportion of the variance of expected inflation in our model. To verify this implication of our model with the data, we

⁹The autocorrelations of inflation only modestly vary across regimes, with the first-order autocorrelation of inflation being highest in regime $s_t = 1$ at 0.77 and lowest in regime $s_t = 4$ at 0.74.

project inflation onto the short rate, spread, and past inflation both in the data and in the model. Panel B of Table 4 reports these results. When the short rate increases by 1%, the model signals an increase in expected inflation of 39 basis points. A 1% increase in the spread predicts an 8 basis point decrease in expected inflation. These patterns are consistent with what is observed in the data, but the response to an increase in the spread is somewhat stronger in the data. Past inflation has a coefficient of 0.52, matching the data coefficient of 0.49 almost exactly.

The model also matches other predictive regressions of future inflation. For example, Mishkin (1990) regresses the difference between the future n -period inflation rate and the one-period inflation rate onto the the n -quarter term spread. In the data, this coefficient takes on a value of 0.98 with a standard error of 0.36 for a horizon of one year. The model-implied coefficient is 0.97. Thus, we are confident that the model matches the dynamics of expected inflation well.

Regime Interpretation

How do we interpret the behavior of the regime variable in economic terms? In Table 5, we describe the behavior of real short rates, one-quarter ahead inflation compensation (which is virtually identical to one-period expected inflation except for Jensen’s inequality terms), and nominal short rates across regimes. This information leads to the following regime characterization:

		Real Short Rates	Inflation	% Time
$s_t = 1$	$s_t^f = 1, s_t^\pi = 1$	Low and Stable	High and Stable	72%
$s_t = 2$	$s_t^f = 1, s_t^\pi = 2$	High and Stable	Low and Stable	4%
$s_t = 3$	$s_t^f = 2, s_t^\pi = 1$	Low and Volatile	High and Volatile	20%
$s_t = 4$	$s_t^f = 2, s_t^\pi = 2$	High and Volatile	Low and Volatile	4%

All the levels (low or high) and variability (stable or volatile) are relative statements, so caution must be taken in the interpretation. The last column lists the proportion of time spent in each regime in the sample based on the population stable probabilities.¹⁰ The means of both real rates and inflation are driven mostly by the s_t^π regime, while their volatilities are driven by the s_t^f regime.

The first regime is a low real rate-high inflation regime, where both real rates and inflation are not very volatile. We spend most of our time in this regime. As we will see, it is better

¹⁰ If we identify the regimes through the sample by using the ex-post smoothed regime probabilities, then we spend less time in regime $s_t = 1$ in sample than the population frequency. Unlike traditional two-regime estimations, like Gray (1996) and Bansal and Zhou (2002), this is not caused purely by switching out of $s_t = 1$ during the monetary targeting period of 1979-1982. In contrast, our model produces more recurring switches into regimes $s_t = 2$ and $s_t = 4$ also occur during the early 1990s and early 2000s, which we discuss below.

to characterize the relatively high inflation regime as a “normal regime” and the low inflation regime as a “disinflation regime.” The volatilities of real short rates, inflation compensation, and nominal short rates are all lowest in regime 1. The regime with the second largest stable probability is regime 3, which is also a low real rate regime. In this regime, the mean of inflation compensation is highest. Thus, in population we spend around 90% of the time in low real rate environments. Regimes 2 and 4 are characterized by relatively high and volatile real short rates. The inflation compensation in these regimes is relatively low. Table 5 shows that these regimes are also associated with downward sloping term structures of real yields. Consequently, the transition probability estimates imply that passing through a downward sloping real yield curve is necessary to reach the regime with relatively low inflation. Finally, regime 4 has the highest volatility of real rates, inflation compensation, and nominal rates.

Regimes Over Time

In Figure 1, we plot the short rate, long rate, and inflation over the sample in the top panel and the smoothed regime probabilities in the bottom panel over the sample period. From 1952 to 1978, the estimation switches between $s_t = 1$ and $s_t = 3$. Recall that these regimes feature relatively low real rates and high inflation. In regime 3, inflation has its highest mean and is quite volatile, leading to high and volatile nominal rates. These regimes precede the recessions of 1960, 1970 and 1975.

Post-1978, the model switches between all four regimes. The period around 1979-1982 of monetary targeting is mostly associated with regime 4, characterized by the highest volatility of real rates and inflation and a downward sloping real yield curve. Before the economy transitions to regime $s_t = 2$ in 1982, with high real rates and low and more stable inflation, there are a few jumps into the higher inflation regime 3.

Post-1982, the regimes 2 and 4, with lower expected inflation, occur regularly. These regimes are associated with rapid decreases in inflation and downward sloping real yield curves. From a Taylor (1993) rule perspective, these regimes may reflect periods where an activist monetary policy of raising real rates, especially through actions at the short-end of the yield curve, achieved disinflation. There are several features of the occurrence of these regimes consistent with this interpretation. First, transitioning into regimes 2 and 4 requires high real rates. Second, these regimes only occur after the Volcker period, which is consistent with the economic arguments of Nelson (2004) and Meltzer (2005), who argue that only after 1979, US monetary authorities had sufficient credibility to change inflation behavior. Third, it also consistent with the econometric analysis of the Taylor rule in Bikbov (2005), Boivin (2006), and Cho and Moreno (2006), among others, who document a structural break from accommodating

to activist monetary policies around 1980.

Towards the end of the 1980s we transition back to the normal regime 1, but just before the 1990-1991 recession, the economy enters into regime 4, followed by regime 2, which lasts until 1994. During the late 1990s, the normal regime $s_t = 1$ prevails with normal, stable inflation and low real rates. During the early 2000s, quarter-on-quarter inflation was briefly negative, and the model transitions to the disinflation regimes $s_t = 2$ and $s_t = 4$ around the time of the 2001 recession. At the end of the sample, December 2004, the model seems to be transitioning back to the normal $s_t = 1$ regime.

In Figure 2, we sum the four s_t regimes into their s_t^f and s_t^π sources. In the top panel, we graph the real short and long 20-quarter real rates, together with one-period expected inflation and long-term inflation compensation for comparison. The real short rate exhibits considerable short-term variation, sometimes decreasing and increasing sharply. There are sharp decreases of real rates in the 1958 and 1975 recessions and after the 2001 recession. Real rates are highly volatile around the 1979-1982 period and increase sharply during the 1980 and 1983 recessions.¹¹ Consistent with the older literature like Mishkin (1981), real rates are generally low from the 1950s until 1980. The sharp increase in the early 1980s up to above 7% was temporary, but it took until after 2001 before real rates reached the low levels common before 1980. Over 1961-1986, Garcia and Perron (1996) find three non-recurring regimes for real rates: 1961-1973, 1973-1980, and 1980-1986. In Figure 2, these periods roughly align with low but stable real rates, very low to negative and volatile real rates, and high and volatile real rate periods. We generate this behavior with recurring s_t^f and s_t^π regimes. The Garcia-Perron model could not generate the gradual decrease in real rates observed since the 1980s. The long real rate shows less time variation, but the same secular effects that drive the variation of the short real rate are visible.

In the middle panel of Figure 2, we plot the smoothed regime probabilities for the regime $s_t^f = 1$, which is the low volatility f_t regime associated with relatively high nominal term spreads. The high variability $s_t^f = 2$ regime occurs just prior to the 1960 recession, during the OPEC oil shocks of the early 1970s, during the 1979-1982 period of monetary targeting, during the 1984 Volcker disinflation, in the 1991 recession, briefly in 1995, and in 2000.

In the bottom panel of Figure 2, the smoothed regime probabilities of s_t^π look very different from the regime probabilities of s_t^f , indicating the potential importance of separating the real and inflation regime variables. We transition to $s_t^\pi = 2$, the disinflation regime, only after 1979 with the 1979-1982 period featuring some sudden, short-lived transitions to $s_t^\pi = 2$. The

¹¹ The 95% standard error bands computed using the delta method are very tight and well within 20 basis points, so we omit them for clarity.

second inflation regime also occurs after 1985, during a sustained period in the early 1990s, and after 2000. In this last recession, there were significant risks of deflation. Clearly, the model accommodates rapid decreases in inflation by a transition to the second regime.¹²

Standard two-regime models of nominal interest rates (both empirical and term structure models), predominantly pick up the late 1970's and early 80's as one regime change. These two-regime models identify the pre-1979 period and the period after the mid-1980s as a low mean, low volatility regime (see, for example, Gray (1996), Ang and Bekaert (2002a), and Dai, Singleton and Yang (2006)). Our regimes for real factors and inflation have more frequent switches than two-regime models. In fact, the famous 1979-1982 episode is a period of both high real rates and high inflation in the late 1970s (regime 3), combined with high real rates and a transition to the second inflation regime caused by a dramatic decrease in inflation in the early 1980s (regime 4). Hence, our regime identification does not seem to be driven by a single period, but rather reflects a series of recurring regimes.

4 The Term Structure of Real Rates and Expected Inflation

We describe the behavior of real yields in Section 4.1. Section 4.2 discusses the behavior of expected inflation and inflation risk premia. Combining real yields with expected inflation and inflation risk premia produces the nominal yield curve, which we discuss in Section 4.3, before turning to variance decompositions in Section 4.4.

4.1 The Behavior of Real Yields

The Real Term Structure

We examine the real term structure in Figure 3 and Table 6. Figure 3 graphs the regime-dependent real term structure. Every point on the curve for regime i represents the expected real zero coupon bond yield conditional on regime i , ($E[\hat{y}_t^n | s_t = i]$).¹³ The unconditional real yield curve is graphed in the circles, which shows a slightly humped real curve peaking around a 1-year maturity before converging to 1.3%. Panel A of Table 6 reports that in the normal regime

¹² The inflation regime identifications of Evans and Wachtel (1993) and Evans and Lewis (1995) are not directly comparable as their models feature a random walk component in one regime (with no drift) and an AR(1) model in the other.

¹³ Appendix G details the computation of these conditional moments. It is also possible to compute the more extreme case $E[\hat{y}_t^n | s_t = i, \forall t]$, that is, assuming that the process never leaves regime i . These curves have similar shapes to the ones shown in the figures but lie at different levels.

($s_t = 1$), the long-term rate curve assumes the same shape but is shifted slightly downwards, ranging from 1.14% at a 3-month horizon to 1.29% at a 5-year horizon.

In regimes 2 and 4, real rates start just below 2% at a 1-quarter maturity and decline to 1.59% for regime 2 and 1.52% for regime 4 at a 20-quarter maturity. Finally, regime 3, a low real rate-high inflation and volatile regime, has a humped, nonlinear, real term structure. This real yield curve peaks at 1.54% at the 1-year maturity before declining to the same level as the unconditional yield curve at 20 quarters. Thus, we uncover our first claim:

Claim 1 *Unconditionally, the term structure of real rates assumes a fairly flat shape around 1.3%, with a slight hump, peaking at a 1-year maturity. However, there are some regimes in which the real rate curve is downward sloping.*

Panel A of Table 6 also reports that while the standard deviation of real short rates are lowest in regime 1 at 1.40%, the standard deviations of real long rates are approximately the same across regimes, at 0.55%. We compute unconditional moments of real yields in Panel B, which shows that the unconditional standard deviation of the real short rate (20-quarter real yield) is 1.46% (0.55%). These moments solidly reject the hypothesis that the real short rate is constant, but at long horizons real yields are much more stable and persistent. This is reflected in the autocorrelations of the real short rate and 20-quarter real rate, which are 60% and 94%, respectively. The mean of the 20-quarter real term spread is only 7 basis points. The standard error is only 28 basis points, so that the real term structure cannot account for the 1.00% nominal term spread in the data. Hence:

Claim 2 *Real rates are quite variable at short maturities but smooth and persistent at long maturities. There is no significant real term spread.*

The Correlation of Real Rates and Inflation

Panel C of Table 6 reports conditional and unconditional correlations of real rates and inflation. At the 1-quarter horizon, the conditional correlation of real rates with actual inflation is negative in all regimes and hence also unconditionally. The negative estimate for δ_π mostly drives this result. The correlations with expected inflation are smaller in absolute value, but still mostly negative. However, the differences across regimes are not large in economic terms and the correlations are overall not significantly different from zero. Consequently, we do not find strong statistical evidence for a Mundell-Tobin effect:

Claim 3 *The real short rate is negatively correlated with both expected and unexpected inflation, but the statistical evidence for a Mundell-Tobin effect is weak.*

This negative correlation between real rates and inflation is consistent with earlier studies such as Huizinga and Mishkin (1986) and Fama and Gibbons (1982), but their analysis implicitly assumes a zero inflation risk premium so their instrumented real rates may partially embed inflation risk premiums. The small Mundell-Tobin effect we estimate is consistent with Pennachi (1991), who uses a two-factor affine model of real rates and expected inflation, but opposite in sign to Barr and Campbell (1997), who use U.K. interest rates and find that the unconditional correlation between real rates and inflation is small but positive. As each regime records a negative correlation between real rates and inflation, we do not find any evidence that the sign of the correlation has changed over time, unlike what Goto and Torous (2006) find using an empirical model that does not employ term structure information or preclude arbitrage.

The correlations between real yields and actual or expected inflation robustly turn positive at long horizons. Some of these correlations are statistically significant, although most are again not precisely estimated. The positive signs at long horizons result from the positive feedback effect of the Φ coefficients dominating the negative effect of the δ_π coefficient in the short rate equation. This indicates that the Mundell-Tobin effect is only a short-horizon phenomenon. Over long horizons, real yields and inflation are positively correlated.

A commonly-imposed restriction in structural models on the relation between inflation and real rate is that the effect of inflation on real rates is relatively short lived. Figure 4 graphs impulse responses of one- and 20-quarter real yields to factor shocks (q , f , and π). The impact of inflation shocks on both the short and the long real rate dies out quickly, while shocks to the price of risk factor, q , and the real rate factor, f , have more persistent effects. In particular, the effect of an inflation shock on real yields lasts less than a year.

The Effect of Regimes on Real Rates

Introducing regimes allows a further nonlinear mapping between latent factors and nominal yields not available in a traditional affine model, so that the dynamics of real long yields are not just linear transformations of nominal yield factors. To compare the effect of incorporating regimes, we contrast our model-implied real yields with those implied by model I_w . Figure 5 plots real yields from models I_w and IV^C and we characterize the differences between the real yields from each model in Table 7.

Panel A of Table 7 reports the population moments of real yields from models I_w and IV^C . The mean real short rate in model I_w is 1.42%, very close to the 1.39% mean of the one-quarter real yield for a similar model estimated by Campbell and Viceira (2001). This is slightly higher, but very similar to the mean level of short rates from our model IV^C , at 1.24%. The standard deviations of real short rates are also similar across the two models, at 1.59% and 1.46%, for

models I_w and IV^C , respectively. However, Model I_w 's real short rates are somewhat more persistent, at 0.72, than the autocorrelation of short rates from model IV^C , at 0.60. There are bigger differences for population moments for real long yields between the models. The real long-end of the yield curve for model I_w is, on average, 40bp higher than for model IV^C and twice as variable, with standard deviations of 1.04% and 0.55%, respectively. The correlation between short and long real rates is higher for model I_w , at 0.79, than for model IV^C , at 0.64. Thus, the addition of regimes has important consequences for inferring long real rates.

Figure 5 plots the real short and long yields over the sample from the two models. The top panel shows that the real short rates from models I_w and IV^C follow the same secular trends, but the correlation between the two model implied real rates is only 0.57. The main difference occurs during the late 1970s. Model IV^C documents that real short rates were fairly low during this period, consistent with the early estimates of Mishkin (1981) and Garcia and Perron (1986). In contrast, model I_w 's real rates are much higher during this period. To quantify these differences, Panel B of Table 7 reports summary statistics on the difference between \hat{r}_t from model I_w and \hat{r}_t from model IV^C . The largest difference of 6.01% occurs during the 1974 recession. In the bottom panel of Figure 5, we graph the real long yield from the two models. While the higher variability of the I_w -implied real long yield is apparent, the two models clearly share the same trends. In fact, the real long rates from the two models have a 0.95 correlation.

In a traditional affine model, there is a direct linear mapping between the latent factors and nominal yields, which may imply that real rates, which are linear combinations of the latent factors, are highly correlated with nominal yields. This is the case for model I_w . The bottom panel of Figure 5 shows that real long yields from model I_w start from below zero in 1952 and reach close to 5% in 1981, before declining to 30bp in 2005. These long real rates are highly correlated with long nominal rates, with a correlation coefficient of 0.98. Incorporating regimes in model IV^C reduces the correlation between real and nominal long rates to 90%. In contrast to model I_w , real long yields implied by model IV^C are more stable and have never been negative. This appears a more economically reasonable characterization of real long yields.

4.2 The Behavior of Inflation and Inflation Risk

The Term Structure of Expected Inflation

Table 8 reports some characteristics of inflation compensation, $\pi_{t,n}^e$; expected inflation, $E_t(\pi_{t+n,n})$; and the inflation risk premium, $\varphi_{t,n}$. We focus first on the inflation compensation estimates. The most striking feature in Table 8 is that the term structure of inflation compensation slopes upwards in all regimes. Regime $s_t = 1$ is the normal regime and in this

regime, the inflation compensation spread is $\pi_{t,20}^e - \pi_{t,1}^e = 1.17\%$, very close to the unconditional inflation compensation spread of 1.14%. In regimes $s_t = 2$ and $s_t = 4$, inflation compensation starts at a lower level because these are the regimes with downward sloping real yield curves and a disinflationary environment. However, the inflation compensation spreads are roughly comparable to the unconditional compensation spread, at 1.34% and 1.16% for regimes $s_t = 2$ and $s_t = 4$, respectively. We report the term structure of expected inflation in the second panel of Table 8. Expected inflation always approaches the unconditional mean of inflation as the horizon increases in all regimes, because inflation is a stationary process.

The Inflation Risk Premium

Since the term structure of inflation compensation is upward sloping but expected inflation converges to long-run unconditional expected inflation, the increasing term structure of inflation compensation is due to an inflation risk premium:

Claim 4 *The model matches an unconditional upward-sloping nominal yield curve by generating an inflation risk premium that is increasing in maturity.*

The third panel of Table 8 reports statistics on the inflation risk premium $\varphi_{t,n}$. In the normal regime $s_t = 1$ and unconditionally, the five-year inflation risk premium is around 1.15%, which is almost the same magnitude as the 5-year term spread generated by the model of 1.21%. The inflation risk premium is higher in regime $s_t = 3$ with higher and more variable inflation than in regime $s_t = 1$. In the high real rate regimes $s_t = 2$ and $s_t = 4$, the inflation risk premium is less than 55 basis points. In regime $s_t = 4$, the inflation risk premium is not statistically different from zero. In Campbell and Viceira's (2001) one-regime setting, $\varphi_{t,40}$ is approximately 0.42%, accounting for about half of their model-implied 40-quarter nominal term spread of 0.88%.¹⁴ We obtain inflation risk premiums of this low magnitude only in high real rate regimes, and in normal times assign almost all of the positive nominal yield spread to inflation risk premiums.

Figure 6 provides some intuition on which parameters have the largest effect on the unconditional 20-quarter inflation risk premium. The risk premium is not very sensitive to δ_π or $\Phi_{\pi q}$. However, increasing the persistence of the inflation process either through $\Phi_{\pi\pi}$ or $\Phi_{\pi f}$ considerably increases $\varphi_{t,n}$. Increasing these parameters would also turn the slightly negative

¹⁴ Campbell and Viceira (1996) report that the difference in expected holding period returns on ten-year nominal bonds over nominal 3-month T-bills in excess of the expected holding period returns on ten-year real bonds over the real 3-month short rate is approximately 1.1% and define this to be the inflation risk premium. In our model, the corresponding number for this quantity at a 20-quarter maturity is $E \left[\ln \left(P_{t+1}^{19} / P_t^{20} \right) - y_t^1 \right] - E \left[\ln \left(\hat{P}_{t+1}^{19} / \hat{P}_t^{20} \right) - \hat{r}_t \right] = 1.46\%$.

correlation between expected inflation and real rates into a positive correlation. The effect of persistence is also stronger than the effect of the price of risk $\lambda_f(s_t^\pi)$. Making the price of risk more negative naturally increases the inflation risk premium, but this would cause the model to grossly over-estimate the nominal term spread.

The time variation of the inflation risk premium is correlated with the time variation of the price of risk factor, q_t , but the correlation of the inflation risk premium with q_t is small, at 9.5% for a 20-quarter maturity. To calculate the proportion of the variance of $\varphi_{t,20}$ due to regime changes, we compare the unconditional variance of $\varphi_{t,20}$ varying across all four regimes with the variance of $\varphi_{t,20}$ if the model never switched from $s_t = 1$. We find that a significant fraction, namely 40%, of the variation of $\varphi_{t,20}$ is due to regime changes.

Figure 7 graphs the 20-quarter inflation risk premium over time and shows that the inflation risk premium decreased in every recession. During the 1981-83 recession, the inflation premium is very volatile, increasing and decreasing by over 75 basis points. The general trend is that the premium rose very gradually from the 1950s until the late 1970s before entering a very volatile period during the monetary targeting period from 1979 to the early 1980s. It is then that the premium reached a peak of 2.04%. While the trend since then has been downward, there have been large swings in the premium. From a temporary low of 50 basis points in the mid-1980s it shot above 1%, coinciding with the halting of the large dollar appreciation of the early 1980s. The inflation premium dropped back to around 50 basis points after the 1987 stock market crash and reached a low of 0.38% in 1993. The sharp drops in the inflation risk premium coincide with transitions to regimes with high real short rates. During 1994, the premium shot back up to 1.37% at the same time the Federal Reserve started to raise interest rates. During the late 1990s bull market inflation risk premiums were fairly stable and declined to 0.15% after the 2001 recession when there were fears of deflation. At the end of the sample in December 2005, the inflation risk premium started to increase again edging close to 1%.

4.3 Nominal Term Structure

Figure 8 graphs the average nominal yield curve. The unconditional yield curve is upward sloping, with the slope flattening out for longer maturities. The benchmark model produces a nominal term spread of $y_t^{20} - y_t^1 = 1.21\%$, well inside a one standard error bound of the 1.00% term spread in data. Strikingly, in no regime does the benchmark model generate a conditional downward sloping nominal yield curve. In regimes $s_t = 2$ and $s_t = 4$, the real rate term structure is downward sloping, but the upward sloping term structure of inflation risk premiums completely counteracts this effect. Thus, regimes are important for the shape of the real, not

nominal yield curve.

The first regime (low real rate-normal inflation regime) displays a nominal yield curve that almost matches the unconditional term structure. In the second regime, the yield curve is shifted downwards but is more steep because rates are lower than in the first regime due to lower expected inflation and inflation risk. In the third regime, the term structure is steeply upward sloping at the short end but then becomes flat and slightly downward sloping for maturities extending beyond 10 quarters. Nominal interest rates are the highest in this regime because in this regime, expected inflation is high and the level of real rates is about the same as in regime 1. In regime 4, the real interest rate curve is downward sloping starting at a high level. Inflation compensation, however, is low in this regime (resulting in nominal yields of an average level), and is upward sloping, making the nominal yield curve upward sloping on average. Yet, in both regimes 2 and 4, a slight J-curve effect is visible at short maturities with nominal rates decreasing slightly before starting to increase.

Interest rates are often associated with the business cycle. The business cycle dates reported by the NBER are regarded as benchmark dates by both academics and practitioners. According to the conventional wisdom, interest rates are pro-cyclical and spreads counter-cyclical (see, for example, Fama (1990)). Table 9 shows that this is incorrect when measuring business cycles using NBER recessions and expansions. Interest rates are overall larger during NBER recessions. However, when we focus on real rates, the conventional story is right:

Claim 5 *Nominal interest rates do not behave pro-cyclically across NBER business cycles but our model-implied real rates do.*

This can only be the case if expected inflation is counter-cyclical. The table shows that this is indeed the case, with inflation compensation being strongly counter-cyclically, averaging 4.73% in recessions but only 3.57% in expansions. Veronesi and Yared (1999) also find that real rates are pro-cyclical in a RS model. In contrast, the real rates implied by model I_w are actually counter-cyclical, averaging 1.58% (1.80%) across NBER expansions (recessions). Thus, the presence of the regimes helps to induce the pro-cyclical behavior of real rates. Finally, Table 9 also illustrates that recessions are characterized by more volatility in real rates, nominal rates, and inflation.

4.4 Variance Decompositions

Table 10 reports the population variance decomposition of the nominal yield into real and inflation compensation. The conditional variance decompositions are very similar across the regimes and so are not reported. The results show that

Claim 6 *The decompositions of nominal yields into real yields and inflation components at various horizons indicate that variation in inflation compensation (expected inflation and inflation risk premia) explains about 80% of the variation in nominal rates at both short and long maturities.*

This is at odds with the folklore wisdom that expected inflation primarily affects long-term bonds (see, among others, Fama (1975) and Mishkin (1981)). The single-regime model I_w attributes even less of the variance of long-term yields to inflation components: at a 20-quarter maturity variation in real yields account for 37% of movements in nominal rates compared to 28% at a 1-quarter maturity. This may be caused by the poor match of inflation dynamics using an affine model calibrated to inflation data. Pennachi's (1991) affine model identifies expected inflation from survey data and finds that expected inflation and inflation risk shows little variation across horizons. Table 10 also reports that the inflation risk premium accounts for 10% of the variance of a 20-quarter maturity nominal yield.

In Table 11, we decompose the variation of nominal term spreads into real rate, expected inflation, and inflation risk premium components. Unconditionally, inflation components account for 49% of the 4-quarter term spread and 80% of the 20-quarter term spread variance. For term spreads, inflation shocks only dominate at the long-end of the yield curve. In the regimes with relatively stable real rates (regimes 1 and 2), inflation components account for over 100% of the variance of long-term spreads. In regimes 3 and 4, real rates are more volatile, and expected inflation accounts for approximately 35% of the variation in the 4-quarter term spread, increasing to over 70% for the 20-quarter term spread. Hence, the conventional wisdom that inflation is more important for the long end of the yield curve holds, not for the level of yields, but for term spreads:

Claim 7 *Inflation compensation is the main determinant of nominal interest rate spreads at long horizons.*

The intuition behind this result is that the long and short end of nominal yields have large exposure to common factors, including the factors driving inflation and inflation risk. It is only after controlling for an average effect, or by computing a term spread, that we can observe relative differences at different parts of the yield curve. Thus, only after computing the term spread do we isolate the factors differentially affecting long yields controlling for the short rate exposure. The finding that inflation components are the main driver of term spreads is not dependent on having regimes in the term structure model. Mishkin (1990, 1992) finds consistent evidence with simple regressions using inflation changes and term spreads, as do

Ang, Dong and Piazzesi (2006) in a single-regime affine model. In model I_w , the attribution of the unconditional variance the 20-quarter term spread to the variation in inflation compensation is also close to 100%.

5 Conclusion

In this article, we develop a term structure model that embeds regime switches in both real and nominal factors, and incorporates time-varying prices of risk. The model that provides the best fit with the data has correlated regimes coming from separate real factor and inflation sources.

We find that the real rate curve is fairly flat but slightly humped, with an average real rate of around 1.3%. The real short rate has an unconditional variability of 1.46% and has an autocorrelation of 60%. In some regimes, the real rate curve is downward sloping. In these regimes, expected inflation is low. The term structure of inflation compensation, the difference between nominal and real yields, is upward sloping. This is due to an upward sloping inflation risk premium, which is unconditionally 1.14% on average. We find that expected inflation and inflation risk account for 80% of the variation in nominal yields at both short and long maturities. However, nominal term spreads are primarily driven by changes in expected inflation, particularly during normal times.

It is interesting to note that our results are qualitatively consistent with Roll's (2004) analysis on TIPS data, over the very short sample period since TIPS began trading. Consistent with our results, Roll also finds that the nominal yield curve is more steeply sloped than the real curve, which is also mostly fairly flat over our over-lapping sample periods. Roll also shows direct evidence of an inflation premium that increases with maturity.

Our work here is only the beginning of a research agenda. In future work, we could use our model to link the often discussed deviations from the Expectations Hypothesis (see, for example, Campbell and Shiller (1991)) to deviations from the Fisher hypothesis (Mishkin (1992)). Although we have made one step in the direction of identifying the economic sources of regime switches in interest rates, more could be done. In particular, a more explicit examination of the role of business cycle variation and changes in monetary policy as sources of the regime switches is an interesting topic for further research.

Appendix

A Modeling Separate f and π Regimes: Case B

For completeness, we first state the case of independent regimes for s_t^f and s_t^π as Case A. In this case,

$$Pr(s_{t+1}^f = j, s_{t+1}^\pi = k | s_t^f = m, s_t^\pi = n) = Pr(s_{t+1}^f = j | s_t^f = m) \times Pr(s_{t+1}^\pi = k | s_t^\pi = n). \quad (\text{A-1})$$

Denoting $Pr(s_{t+1}^f = 1 | s_{t+1}^\pi = 1) = p^f$, $Pr(s_{t+1}^\pi = 1 | s_{t+1}^f = 1) = p^\pi$, $Pr(s_{t+1}^f = 2 | s_{t+1}^\pi = 2) = q^f$, and $Pr(s_{t+1}^\pi = 2 | s_{t+1}^f = 2) = q^\pi$ gives rise to a restricted transition probability matrix Π :

	$[s_{t+1} = 1]$	$[s_{t+1} = 2]$	$[s_{t+1} = 3]$	$[s_{t+1} = 4]$
$[s_t = 1]$	$p^f p^\pi$	$p^f (1 - p^\pi)$	$(1 - p^f) p^\pi$	$(1 - p^f) (1 - p^\pi)$
$[s_t = 2]$	$p^f (1 - q^\pi)$	$p^f q^\pi$	$(1 - p^f) (1 - q^\pi)$	$(1 - p^f) q^\pi$
$[s_t = 3]$	$(1 - q^f) p^\pi$	$(1 - q^f) (1 - p^\pi)$	$q^f p^\pi$	$q^f (1 - p^\pi)$
$[s_t = 4]$	$(1 - q^f) (1 - q^\pi)$	$(1 - q^f) q^\pi$	$q^f (1 - q^\pi)$	$q^f q^\pi$

(A-2)

In Case B of Section 2.2, s_t^f and s_t^π are correlated and we decompose the joint transition probability of f and π regimes as:

$$\begin{aligned} & Pr(s_{t+1}^f = j, s_{t+1}^\pi = k | s_t^f = m, s_t^\pi = n) \\ &= Pr(s_{t+1}^f = j | s_{t+1}^\pi = k, s_t^f = m, s_t^\pi = n) \times Pr(s_{t+1}^\pi = k | s_t^f = m, s_t^\pi = n) \\ &= Pr(s_{t+1}^f = j | s_{t+1}^\pi = k, s_t^f = m) \times Pr(s_{t+1}^\pi = k | s_t^\pi = n) \end{aligned} \quad (\text{A-3})$$

In the last line, we assume that the past inflation regime does not determine the contemporaneous correlation of the f_t and the π_t regime. Mathematically, we assume that $Pr(s_{t+1}^f = j | s_{t+1}^\pi = k, s_t^f = m, s_t^\pi = n) = Pr(s_{t+1}^f = j | s_{t+1}^\pi = k, s_t^f = m)$. We also assume that $Pr(s_{t+1}^\pi = k | s_{t+1}^f = m, s_t^\pi = n) = Pr(s_{t+1}^\pi = k | s_{t+1}^f = m)$, or that the past real rate f_t factor regime does not influence future inflation regime realizations.

In equation (A-3), we parameterize $Pr(s_{t+1}^f = j | s_{t+1}^\pi = k, s_t^f = m)$ as $p^{“j”, “m”}$, where:

$$j = \begin{cases} A & \text{if } s_{t+1}^f = s_{t+1}^\pi = 1 \\ B & \text{if } s_{t+1}^f = s_{t+1}^\pi = 2 \end{cases}$$

$$m = \begin{cases} A & \text{if } s_t^f = 1 \\ B & \text{if } s_t^f = 2. \end{cases}$$

With this notation, the transition probability matrix Π assumes the form:

	$[s_{t+1} = 1]$	$[s_{t+1} = 2]$	$[s_{t+1} = 3]$	$[s_{t+1} = 4]$
$[s_t = 1]$	$p^{AA} p^\pi$	$(1 - p^{BA}) (1 - p^\pi)$	$(1 - p^{AA}) p^\pi$	$p^{BA} (1 - p^\pi)$
$[s_t = 2]$	$p^{AA} (1 - q^\pi)$	$(1 - p^{BA}) q^\pi$	$(1 - p^{AA}) (1 - q^\pi)$	$p^{BA} q^\pi$
$[s_t = 3]$	$p^{AB} p^\pi$	$(1 - p^{BB}) (1 - p^\pi)$	$(1 - p^{AB}) p^\pi$	$p^{BB} (1 - p^\pi)$
$[s_t = 4]$	$p^{AB} (1 - q^\pi)$	$(1 - p^{BB}) q^\pi$	$(1 - p^{AB}) (1 - q^\pi)$	$p^{BB} q^\pi$

(A-4)

This model has four additional parameters relative to the benchmark model. We can test the null of independent real rate and inflation regimes versus correlated regimes by:

$$H_0 : p^{BA} = 1 - p^{AA} \text{ and } p^{BB} = 1 - p^{AB}.$$

In our estimation, we reject the null of independent regimes in equation (A-1) against the alternative of Case B, but this model provides a worse fit to the data than Case C.

B Real Bond Prices

Let N_1 be the number of unobserved state variables in the model ($N_1 = 3$ for the stochastic inflation model, $N_1 = 2$ otherwise) and $N = N_1 + 1$ be the total number of factors including inflation. The following proposition describes how our model implies closed-form real bond prices.

Proposition B.1 *Let $X_t = (q_t f_t \pi_t)'$ or $X_t = (q_t f_t w_t \pi_t)'$ follow (2), with the real short rate (4) and real pricing kernel (5) with prices of risk (6). The regimes s_t follow a Markov chain with transition probability matrix $\Pi = \{p_{ij}\}$. Then the real zero coupon bond price for period n conditional on regime i , $\hat{P}_t^n(s_t = i)$, is given by:*

$$\hat{P}_t^n(i) = \exp(\hat{A}_n(i) + \hat{B}_n X_t). \quad (\text{B-1})$$

The scalar $\hat{A}_n(i)$ is dependent on regime $s_t = i$ and \hat{B}_n is a $1 \times N$ vector that is partitioned as $\hat{B}_n = [\hat{B}_{nq} \hat{B}_{nx}]$, where \hat{B}_{nq} corresponds to the q variable and \hat{B}_{nx} corresponds to the other variables in X_t . The coefficients $\hat{A}_n(i)$ and \hat{B}_n are given by:

$$\begin{aligned} \hat{A}_{n+1}(i) &= - \left(\delta_0 + \hat{B}'_{nq} \sigma_q \gamma_0 \right) + \log \sum_j p_{ij} \exp \left(\hat{A}_n(j) + \hat{B}_n \mu(j) \right) \\ &\quad - \hat{B}_{nx} \Sigma_x(j) \lambda(j) + \frac{1}{2} \hat{B}_n \Sigma(j) \Sigma(j)' \hat{B}'_n \\ \hat{B}_{n+1} &= - \delta'_1 + \hat{B}_n \Phi - \hat{B}_{nq} \sigma_q \gamma_1 e'_1, \end{aligned} \quad (\text{B-2})$$

where e_i denotes a vector of zero's with a 1 in the i th place and $\Sigma_x(i)$ refers to the lower $N_1 \times N_1$ matrix of $\Sigma(i)$ corresponding to the non- q_t variables in X_t . The starting values for $\hat{A}_n(i)$ and \hat{B}_n are:

$$\begin{aligned} \hat{A}_1(i) &= -\delta_0 \\ \hat{B}_1 &= -\delta'_1. \end{aligned} \quad (\text{B-3})$$

Proof:

We first derive the initial values in (B-3):

$$\begin{aligned} P_t^1(i) &= \sum_j p_{ij} E_t \left[\widehat{M}_{t+1} | S_{t+1} = j \right] \\ &= \sum_j p_{ij} \exp \left(-r_t - \frac{1}{2} \lambda_t(j)' \lambda_t(j) - \lambda_t(j)' \varepsilon_{t+1} \right) \\ &= \exp(-\delta_0 - \delta'_1 X_t) \end{aligned} \quad (\text{B-4})$$

Hence:

$$\hat{P}_t^1(i) = \exp(\hat{A}_1(i) + \hat{B}_1 X_t),$$

where $A_1(i)$ and B_1 take the form in (B-3).

We prove the recursion (B-2) by induction. We assume that (B-1) holds for maturity n and examine $\hat{P}_t^{n+1}(i)$:

$$\begin{aligned} \hat{P}_t^{n+1}(i) &= \sum_j p_{ij} E_t \exp \left[-r_t - \frac{1}{2} \lambda_t(j)' \lambda_t(j) - \lambda_t(j)' \varepsilon_{t+1} + \hat{A}_n(j) + \hat{B}_n X_{t+1} \right], \\ &= \sum_j p_{ij} E_t \exp \left[-\delta_0 - \delta'_1 X_t - \frac{1}{2} \lambda_t(j)' \lambda_t(j) - \lambda_t(j)' \varepsilon_{t+1} + \hat{A}_n(j) \right. \\ &\quad \left. + \hat{B}_n (\mu(j) + \Phi X_t + \Sigma(j) \varepsilon_{t+1}) \right] \end{aligned} \quad (\text{B-5})$$

Evaluating the expectation, we have:

$$\begin{aligned}
\widehat{P}_t^{n+1}(i) &= \sum_j p_{ij} \exp \left[-\delta_0 - \delta'_1 X_t - \frac{1}{2} \lambda_t(j)' \lambda_t(j) + \widehat{A}_n(j) + \widehat{B}_n \mu(j) \right. \\
&\quad \left. + \widehat{B}_n \Phi X_t + \frac{1}{2} \left(\widehat{B}_n \Sigma(j) - \lambda_t(j)' \right) \left(\widehat{B}_n \Sigma(j) - \lambda_t(j)' \right)' \right] \\
&= \exp \left[-\delta_0 + \left(\widehat{B}_n \Phi - \delta'_1 \right) X_t \right] \\
&\quad \times \sum_j p_{ij} \exp \left[\widehat{A}_n(j) + \widehat{B}_n \mu(j) - \widehat{B}_n \Sigma(j) \lambda_t(j) + \frac{1}{2} \widehat{B}_n \Sigma(j) \Sigma(j) \widehat{B}_n' \right] \tag{B-6}
\end{aligned}$$

But, we can write:

$$\begin{aligned}
\widehat{B}_n \Sigma(j) \lambda_t(j) &= [\widehat{B}_{nq} \widehat{B}_{nx}] \begin{bmatrix} \sigma_q (\gamma_0 + \gamma_1 e'_1 X_t) \\ \Sigma_x(j) \lambda(j) \end{bmatrix} \\
&= \widehat{B}_{nq} \sigma_q (\gamma_0 + \gamma_1 e'_1 X_t) + \widehat{B}_{nx} \Sigma_x(j) \lambda(j). \tag{B-7}
\end{aligned}$$

Then, expanding and collecting terms, we can write:

$$\widehat{P}_t^n(i) = \exp(\widehat{A}_n(i) + \widehat{B}_n X_t),$$

where $\widehat{A}_n(i)$ and \widehat{B}_n take the form of (B-2). ■

C Nominal Bond Prices

Following the notation of Appendix B, let N_1 be the number of unobserved state variables in the model ($N_1 = 3$ for the stochastic inflation model, $N_1 = 2$ otherwise) and $N = N_1 + 1$ be the total number of factors including inflation. The following proposition describes how our model implies closed-form nominal bond prices.

Proposition C.1 *Let $X_t = (q_t f_t \pi_t)'$ or $X_t = (q_t f_t w_t \pi_t)'$ follow (2), with the real short rate (4) and real pricing kernel (5) with prices of risk (6). The regimes s_t follow a Markov chain with transition probability matrix $\Pi = \{p_{ij}\}$. Then the nominal zero coupon bond price for period n conditional on regime i , $P_t^n(s_t = i)$, is given by:*

$$P_t^n(i) = \exp(A_n(i) + B_n X_t), \tag{C-1}$$

where the scalar $A_n(i)$ is dependent on regime $s_t = i$ and B_n is an $N \times 1$ vector:

$$\begin{aligned}
A_{n+1}(i) &= -(\delta_0 + B'_{nq} \sigma_q \gamma_0) + \log \sum_j p_{ij} \exp \left(A_n(j) + (B_n - e'_{N_1}) \mu(j) \right. \\
&\quad \left. - (B_{nx} - e'_{N_1}) \Sigma_x(j) \lambda(j) + \frac{1}{2} (B_n - e'_{N_1}) \Sigma(j) \Sigma(j) (B_n - e'_{N_1})' \right) \\
B_{n+1} &= -\delta'_1 + (B_n - e'_{N_1}) \Phi - B_{nq} \sigma_q \gamma_1 e'_1, \tag{C-2}
\end{aligned}$$

where e_i denotes a vector of zero's with a 1 in the i th place, $A(i)$ is a scalar dependent on regime $s_t = i$, B_n is a row vector, which is partitioned as $B_n = [B_{nq} B_{nx}]$, where B_{nq} corresponds to the q variable and $\Sigma_x(i)$ refers to the lower $N_1 \times N_1$ matrix of $\Sigma(i)$ corresponding to the non- q_t variables in X_t . The starting values for $A_n(i)$ and B_n are:

$$\begin{aligned}
A_1(i) &= -\delta_0 + \log \sum_j p_{ij} \exp \left(-e'_{N_1} \mu(j) + \frac{1}{2} e'_{N_1} \Sigma(j) \Sigma(j)' e_{N_1} + e'_{N_1} \Sigma_x(j) \lambda(j) \right) \\
B_1 &= -(\delta'_1 + e'_{N_1} \Phi). \tag{C-3}
\end{aligned}$$

Proof:

We first derive the initial values (C-3) by directly evaluating:

$$\begin{aligned}
P_t^1(i) &= \sum_j p_{ij} E_t \left[\widehat{M}_{t+1} | S_{t+1} = j \right] \\
&= \sum_j p_{ij} \exp \left(-r_t - \frac{1}{2} \lambda_t(j)' \lambda_t(j) - \lambda_t(j)' \varepsilon_{t+1} - e'_N (\mu(j) + \Phi X_t + \Sigma(j) \varepsilon_{t+1}) \right) \\
&= \exp(-\delta_0 - \delta'_1 X_t - e'_N \Phi X_t) \\
&\quad \times \sum_j p_{ij} \exp \left(-e'_N \mu(j) - e'_N \Sigma(j) \varepsilon_{t+1} - \frac{1}{2} \lambda_t(j)' \lambda_t(j) - \lambda_t(j)' \varepsilon_{t+1} \right) \\
&= \exp(-\delta_0 - \delta'_1 X_t - e'_N \Phi X_t) \\
&\quad \times \sum_j p_{ij} \exp \left(-e'_N \mu(j) + \frac{1}{2} e'_N \Sigma(j) \Sigma(j)' e_N + e'_N \Sigma(j) \lambda_t(j) \right). \tag{C-4}
\end{aligned}$$

Note that $e'_N \Sigma(j) \lambda_t(j) = e'_{N_1} \Sigma_x(j) \lambda(j)$. Hence:

$$P_t^1(i) = \exp(A_1(i) + B_1 X_t)$$

where $A_1(i)$ and B_1 are given by (C-3).

To prove the general recursion we use proof by induction:

$$\begin{aligned}
P_t^{n+1}(i) &= \sum_j p_{ij} E_t \left[\exp \left(-r_t - \frac{1}{2} \lambda_t(j)' \lambda_t(j) - \lambda_t(j)' \varepsilon_{t+1} - e'_N X_{t+1} \right) \right. \\
&\quad \left. \exp(A_n(j) + B_n X_{t+1}) \right] \\
&= \sum_j p_{ij} E_t \left[\exp \left(-\delta_0 - \delta'_1 X_t - \frac{1}{2} \lambda_t(j)' \lambda_t(j) - \lambda_t(j)' \varepsilon_{t+1} + A_n(j) \right. \right. \\
&\quad \left. \left. + (B_n - e'_N) (\mu(j) + \Phi X_t + \Sigma(j) \varepsilon_{t+1}) \right) \right] \\
&= \sum_j p_{ij} \exp \left(-\delta_0 - \delta'_1 X_t - \frac{1}{2} \lambda_t(j)' \lambda_t(j) + A_n(j) + (B_n - e'_N) \mu(j) \right. \\
&\quad \left. + (B_n - e'_N) \Phi X_t + \frac{1}{2} ((B_n - e'_N) \Sigma(j) - \lambda_t(j)') ((B_n - e'_N) \Sigma(j) - \lambda_t(j)')' \right) \\
&= \exp(-\delta_0 + ((B_n - e'_N) \Phi - \delta'_1) X_t) \sum_j p_{ij} \exp \left(A_n(j) + (B_n - e'_N) \mu(j) \right. \\
&\quad \left. - (B_n - e'_N) \Sigma(j) \lambda_t(j) + \frac{1}{2} (B_n - e'_N) \Sigma(j) \Sigma(j) (B_n - e'_N)' \right) \tag{C-5}
\end{aligned}$$

Now note that:

$$\begin{aligned}
(B_n - e'_N) \Sigma(j) \lambda_t(j) &= (B_n - e'_N) \begin{bmatrix} \sigma_q (\gamma_0 + \gamma_1 e'_1 X_t) \\ \Sigma_x(j) \lambda(j) \end{bmatrix} \\
&= \begin{bmatrix} B_{nq} \\ B_{nx} - e'_{N_1} \end{bmatrix} \begin{bmatrix} \sigma_q (\gamma_0 + \gamma_1 e'_1 X_t) \\ \Sigma_x(j) \lambda(j) \end{bmatrix} \\
&= B_{nq} \sigma_q (\gamma_0 + \gamma_1 e'_1 X_t) + (B_{nx} - e'_{N_1}) \Sigma_x(j) \lambda(j) \tag{C-6}
\end{aligned}$$

where $B_n = [B_{nq} \ B_{nx}]$.

Hence, collecting terms and substituting (C-6) into (C-5), we have:

$$P_t^{n+1}(i) = \exp[A_{n+1}(i) + B_{n+1} X_t],$$

where: $A_n(i)$ and B_n are given by (C-2). ■

D Likelihood Function and Identification

Likelihood Function

We specify the set of nominal yields without measurement error as Y_{1t} ($N_1 \times 1$) and the remaining yields as Y_{2t} ($N_2 \times 1$). There are as many yields measured without error as there are latent factors in X_t . The complete set of yields are denoted as $Y_t = (Y'_{1t} Y'_{2t})'$ with dimension $M \times 1$, where $M = N_1 + N_2$. Note that the total number of factors in X_t is $N = N_1 + 1$, since the last factor, inflation, is observable.

Given the expression for nominal yields in (11), the yields observed without error and inflation, $Z_t = (Y'_{1t} \pi_t)'$, take the form:

$$Z_t = \mathcal{A}_1(s_t) + \mathcal{B}_1 X_t, \quad (\text{D-1})$$

where:

$$\mathcal{A}_1(s_t) = \begin{bmatrix} \mathcal{A}_n(s_t) \\ 0 \end{bmatrix} \quad \mathcal{B}_1 = \begin{bmatrix} \mathcal{B}_n \\ e'_N \end{bmatrix}, \quad (\text{D-2})$$

where $\mathcal{A}_n(s_t)$ is the $N_1 \times 1$ vector stacking the $-A_n(s_t)/n$ terms for the N_1 yields observed without error, and \mathcal{B}_n is a $N_1 \times N$ matrix which stacks the $-B_n/n$ vectors for the two yields observed without error. Then we can invert for the unobservable factors:

$$X_t = \mathcal{B}^{-1}(Z_t - \mathcal{A}_1(s_t)) \quad (\text{D-3})$$

Substituting this into (D-1) and using the dynamics of X_t in (2), we can write:

$$Z_t = c(s_t, s_{t-1}) + \Psi Z_{t-1} + \Omega(s_t) \epsilon_t, \quad (\text{D-4})$$

where:

$$\begin{aligned} c(s_t, s_{t-1}) &= \mathcal{A}_1(s_t) + \mathcal{B}_1 \mu(s_t) - \mathcal{B}_1 \Phi \mathcal{B}_1^{-1} \mathcal{A}_1(s_{t-1}) \\ \Psi &= \mathcal{B}_1 \Phi \mathcal{B}_1^{-1} \\ \Omega(s_t) &= \mathcal{B}_1 \Sigma(s_t) \end{aligned}$$

Note that our model implies a RS-VAR for the observable variables with complex cross-equation restrictions.

The yields Y_{2t} observed with error have the form:

$$Y_{2t} = \mathcal{A}_2(s_t) + \mathcal{B}_2 X_t + u_t, \quad (\text{D-5})$$

where \mathcal{A}_2 and $\mathcal{B}_2(s_t)$ follow from Proposition C.1 and u is the measurement error, $u_t \sim N(0, V)$, where V is a diagonal matrix. We can solve for u_t in equation (D-5) using the inverted factor process (D-3). We assume that u_t is uncorrelated with the errors ϵ_t in (2).

Following Hamilton (1994), we redefine the states s_t^* to count all combinations of s_t and s_{t-1} , with the corresponding re-defined transition probabilities $p_{ij}^* = p(s_{t+1}^* = i | s_t^* = j)$. We re-write (D-4) and (D-5) as:

$$\begin{aligned} Z_t &= c(s_t^*) + \Psi Z_{t-1} + \Omega(s_t^*) \epsilon_t, \\ Y_{2t} &= \mathcal{A}_2(s_t^*) + \mathcal{B}_2 X_t + u_t. \end{aligned} \quad (\text{D-6})$$

Now the standard Hamilton (1989, 1994) and Gray (1996) algorithms can be used to estimate the likelihood function. Since (D-6) gives us the conditional distribution $f(\pi_t, Y_{1t}^1 | s_t^* = i, I_{t-1})$, we can write the likelihood as:

$$\begin{aligned} \mathcal{L} &= \prod_t \sum_{s_t^*} f(\pi_t, Y_{1t}, Y_{2t} | s_t^*, I_{t-1}) Pr(s_t^* | I_{t-1}) \\ &= \prod_t \sum_{s_t^*} f(Z_t | s_t^*, I_{t-1}) f(Y_{2t} | \pi_t, Y_{1t}, s_t^*, I_{t-1}) Pr(s_t^* | I_{t-1}) \end{aligned} \quad (\text{D-7})$$

where:

$$\begin{aligned} f(Z_t | s_t^*, I_{t-1}) &= (2\pi)^{-(N_1+1)/2} |\Omega(s_t^*) \Omega(s_t^*)'|^{-1/2} \\ &\quad \exp\left(-\frac{1}{2} (Z_t - c(s_t^*) - \Psi Z_{t-1})' [\Omega(s_t^*) \Omega(s_t^*)']^{-1} (Z_t - c(s_t^*) - \Psi Z_{t-1})\right) \end{aligned}$$

is the probability density function of Z_t conditional on s_t^* and

$$f(Y_{2t}|\pi_t, Y_{1t}, s_t^*, I_{t-1}) = (2\pi)^{-N_2/2} |V|^{-1/2} \exp\left(-\frac{1}{2}(Y_{2t} - \mathcal{A}_2(s_t^*) - \mathcal{B}_2 X_t)' V^{-1} (Y_{2t} - \mathcal{A}_2(s_t^*) - \mathcal{B}_2 X_t)\right)$$

is the probability density function of the measurement errors conditional on s_t^* .

The ex-ante probability $Pr(s_t^* = i|I_{t-1})$ is given by:

$$Pr(s_t^* = i|I_{t-1}) = \sum_j p_{ji}^* Pr(s_{t-1}^* = j|I_{t-1}), \quad (\text{D-8})$$

which is updated using:

$$\begin{aligned} Pr(s_t^* = j|I_t) &= \frac{f(Z_t, s_t^* = j|I_{t-1})}{f(Z_t|I_{t-1})} \\ &= \frac{f(Z_t|s_t^* = j, I_{t-1}) Pr(s_t^* = j|I_{t-1})}{\sum_k f(Z_t|s_t^* = k, I_{t-1}) Pr(s_t^* = k|I_{t-1})} \end{aligned}$$

An alternative way to derive the likelihood function is to substitute (D-3) into (D-5). We then obtain a RS-VAR with complex cross-equation restrictions for all variables in the system $(Z_t' Y_{2t}')'$. Note that unlike a standard affine model, the likelihood is not simply the likelihood of the yields measured without error multiplied by the likelihood of the measurement errors. Instead, the regime variables must be integrated out of the likelihood function.

Identification

There are two identification problems. First, there are the usual identification conditions that must be imposed to estimate a model with latent variables, which have been derived for affine models by Dai and Singleton (2000). In a single-regime Gaussian model, Dai and Singleton show that identification can be accomplished by setting the conditional covariance to be a diagonal matrix and letting the correlations enter through the feedback matrix (Φ), which is parameterized to be lower triangular, which we do here.

The RS model complicates identification relative to an affine model. The parameterization in equations (2)-(7) already imposes some of the Dai and Singleton (200) conditions, but some further restrictions are necessary. Since q_t and f_t are latent variables, they can be arbitrarily scaled. We set $\delta_1 = (\delta_q \delta_f \delta_\pi)' = (1 \ 1 \ \delta_\pi)'$ in (4). Setting δ_q and δ_f to be constants allows σ_q and $\sigma_f(s_{t+1})$ to be estimated. Because q_t is an unobserved variable, estimating μ_q in (3) is equivalent to allowing γ_0 in (6) or δ_0 in (4) to be non-zero. Hence, q_t must have zero mean for identification. Therefore, we set $\mu_q = 0$, since q_t does not switch regimes. Similarly, because we estimate $\lambda_f(s_{t+1})$, we constrain f_t to have zero mean.

The resulting model is theoretically identified from the data, but it is well known that some parameters that are identified in theory can be very hard to estimate in small samples. This is especially true for price of risk parameters. Because we using four nominal yields, we should be able to identify all three prices of risk. However, Dai and Singleton (2000) note that it is typically difficult to identify more than one constant price of risk. Hence, we set $\gamma_0 = 0$ in (6) and instead estimate the RS price of risk $\lambda_f(s_{t+1})$.

We also set $\Phi_{fq} = 0$ in equation (3). With this restriction, there are, in addition to inflation factors, two separate and easily identifiable sources of variation in interest rates: a RS factor and a time-varying price of risk factor. Identifying their relative contribution to interest rate dynamics becomes easy with this restriction and it is not immediately clear how a non-zero coefficient would help enrich the model.

As q_t and f_t are zero mean, the mean level of the real short rate in (4) is determined by the mean level of inflation multiplied by δ_π and the constant term δ_0 . We set δ_0 to match the mean of the nominal short rate in the data, similar to Ang, Dong and Piazzesi (2006) and Dai, Singleton and Yang (2006).

Finally, we set the one-period price of inflation risk equal to zero, $\lambda_\pi(s_{t+1}) = 0$. Theoretically, this parameter is uniquely identified, but in practice the average level of real rates and the premium is largely indeterminate without further restrictions. It turns out that the first-order effect of λ_π on real rates and the inflation risk premium is similar and of opposite sign. Because of this, the parameter is not only hard to pin down, but also essentially prevents the identification of the average level of real rates and the average level of the inflation risk premium. Models with a positive one-period inflation risk premium will imply lower real rates and higher inflation premiums than the results we report.

E A Regime-Switching Model with Stochastic Expected Inflation

In a final extension, motivated by the ARMA-model literature (see Fama and Gibbons, 1982; Hamilton, 1985), we allow inflation to be composed of a stochastic expected inflation term plus a random shock:

$$\pi_{t+1} = w_t + \sigma_\pi \varepsilon_{t+1}^\pi,$$

where $w_t = E_t[\pi_{t+1}]$ is the one-period-ahead expectation of future inflation. This can be accomplished in our framework by expanding the state variables to $X_t = (q_t f_t w_t \pi_t)'$ which follow the dynamics of equation (2), except now:

$$\mu(s_t) = \begin{bmatrix} \mu_q \\ \mu_f(s_t) \\ \mu_w(s_t) \\ 0 \end{bmatrix}, \quad \Phi = \begin{bmatrix} \Phi_{qq} & 0 & 0 & 0 \\ \Phi_{fq} & \Phi_{ff} & 0 & 0 \\ \Phi_{wq} & \Phi_{wf} & \Phi_{ww} & \Phi_{w\pi} \\ 0 & 0 & 1 & 0 \end{bmatrix}, \quad (\text{E-9})$$

and $\Sigma(s_t)$ is a diagonal matrix with $(\sigma_q \sigma_f(s_t) \sigma_w(s_t) \sigma_\pi(s_t))'$ on the diagonal. Note that both the variance of inflation and the process of expected inflation are regime dependent. Moreover, past inflation affects current expected inflation through $\Phi_{w\pi}$.

The real short rate and the regime transition probabilities are the same as in the benchmark model. The real pricing kernel also takes the same form as (5) with one difference. The regime-dependent part of the prices of risk in equation (6) is now given by:

$$\lambda(i) = (\lambda_f(i) \lambda_w(i) \lambda_\pi(i))',$$

but we set $\lambda_w(i) = 0$ for identification.

F Specification Tests

Moment Tests

To enable comparison across several non-nested models of how the moments implied from various models compare to the data, we introduce the point statistic:

$$H = (h - \bar{h})' \Sigma_h^{-1} (h - \bar{h}), \quad (\text{F-1})$$

where \bar{h} are sample estimates of unconditional moments, h are the unconditional moments from the estimated model, and Σ_h is the covariance matrix of the sample estimates of the unconditional moments, estimated by GMM with four Newey-West (1987) lags. In this comparison, the moments implied by various models are compared to the data, with the data sampling error Σ_h held constant across the models. The moments we consider are the first and second moments of term spreads and long yields; the first and second moments of inflation; the autocorrelogram of term spreads; and the autocorrelogram of inflation.

Equation (F-1) ignores the sampling error of the moments of the model, implied by the uncertainty in the parameter estimates, making our moment test informal. However, this allows the same weighting matrix, computed from the data, to be used across different models. If parameter uncertainty is also taken into account, we might fail to reject, not because the model accurately pins down the moments, but because of the large uncertainty in estimating the model parameters.

Residual Tests

We report two tests on in-sample scaled residuals ϵ_t of yields and inflation. The scaled residuals ϵ_t are not the same as the shocks ε_t in (2). For a variable x_t , the scaled residual is given by $\epsilon_t = (x_t - E_{t-1}(x_t)) / \sqrt{\text{var}_{t-1}(x_t)}$, where x_t are yields or inflation. The conditional moments are computed using our RS model and involve ex-ante probabilities $p(s_t = i | I_{t-1})$. Following Bekaert and Harvey (1997), we use a GMM test for serial correlation in scaled residuals ϵ_t :

$$E[\epsilon_t \epsilon_{t-1}] = 0. \quad (\text{F-2})$$

We also test for serial correlation in the second moments of the scaled residuals:

$$E[(\epsilon_t)^2 - 1][(\epsilon_{t-1})^2 - 1] = 0. \quad (\text{F-3})$$

G Computing Moments of the Regime-Switching Model

The formulae given here assume that there are K regimes $s_t = 1, \dots, K$. Timmermann (2000) provides explicit formulae for a similar formulation of (2), except that the conditional mean of X_{t+1} depends on $\mu(s_{t+1}) + \Phi(X_t - \mu(s_t))$ rather than on $\mu(s_{t+1}) + \Phi X_t$. In Timmermann's set-up, $E(X_t|s_t)$ is trivially $\mu(s_t)$, whereas in our model the computation is more complex.

Conditional First Moments $E(X_t|s_t)$

Starting from (2), and taking expectations conditional on s_{t+1} , we have:

$$E(X_{t+1}|s_{t+1}) = E(\mu(s_{t+1})|s_{t+1}) + \Phi E(X_t|s_{t+1}) \quad (\text{G-1})$$

To evaluate $E(X_t|s_{t+1})$ we use Bayes Rule:

$$E(X_t|s_{t+1} = i) = \sum_{j=1}^K E(X_t|s_t = j) Pr(s_t = j|s_{t+1} = i). \quad (\text{G-2})$$

The probability $Pr(s_t = j|s_{t+1} = i)$ is the transition probability of the 'time-reversed' Markov chain that moves backward in time. These backward transition probabilities are given by:

$$Pr(s_t = j|s_{t+1} = i) \triangleq b_{ij} = p_{ji} \left(\frac{\pi_j}{\pi_i} \right),$$

where $p_{ji} = Pr(s_{t+1} = i|s_t = j)$ are the forward transition probabilities and $\pi_i = Pr(s_t = i)$ is the stable probability of regime i . Denote the backward transition probability matrix as $B = \{b_{ij}\}$

Using the backward transition probabilities, (G-1) can be rewritten:

$$E(X_{t+1}|s_{t+1} = i) = \mu(i) + \Phi \sum_{j=1}^K E(X_t|s_t = j) b_{ji}. \quad (\text{G-3})$$

Assuming stationarity, that is $E(X_{t+1}|s_{t+1} = i) = E(X_t|s_t = i)$, and defining the $K \times 1$ vectors:

$$\vec{E}(X_t|s_t) = \begin{bmatrix} E(X_t|s_t = 1) \\ \vdots \\ E(X_t|s_t = K) \end{bmatrix} \quad \text{and} \quad \vec{\mu}(s_t) = \begin{bmatrix} \mu(1) \\ \vdots \\ \mu(K) \end{bmatrix},$$

we can write:

$$\vec{E}(X_t|s_t) = \vec{\mu}(s_t) + \Phi \vec{E}(X_t|s_t) B'.$$

Hence, we can solve for $\vec{E}(X_t|s_t)$ as:

$$\text{vec}[\vec{E}(X_t|s_t)] = (I - B \otimes \Phi)^{-1} \text{vec}[\vec{\mu}(s_t)] \quad (\text{G-4})$$

Conditional Second Moments $E(X_t X_t' | s_t)$

Starting from (2), we can write:

$$X_{t+1} X_{t+1}' = (\mu(s_{t+1}) + \Phi X_t + \Sigma(s_{t+1}) \varepsilon_{t+1})(\mu(s_{t+1}) + \Phi X_t + \Sigma(s_{t+1}) \varepsilon_{t+1})', \quad (\text{G-5})$$

and taking expectations conditional on s_{t+1} , we have:

$$\begin{aligned} E(X_{t+1} X_{t+1}' | s_{t+1}) &= \mu(s_{t+1}) \mu(s_{t+1})' + \Sigma(s_{t+1}) \Sigma(s_{t+1})' \\ &\quad + \mu(s_{t+1}) E(X_t | s_{t+1})' \Phi' + \Phi E(X_t | s_{t+1}) \mu(s_{t+1})' + \Phi E(X_t X_t' | s_{t+1}) \Phi'. \end{aligned} \quad (\text{G-6})$$

We can evaluate the term $E(X_t|s_{t+1})$ from (G-2). Hence, we can define an $N \times N$ matrix $G(i)$:

$$G(i) = \mu(i)\mu(i)' + \Sigma(i)\Sigma(i)' + \mu(i)E(X_t|s_{t+1} = i)\Phi' + \Phi E(X_t|s_{t+1} = i)\mu(i)'. \quad (\text{G-7})$$

Substituting (G-7) into (G-6) and using Bayes' Rule, we have:

$$\begin{aligned} E(X_{t+1}X'_{t+1}|s_{t+1} = i) &= G(i) + \sum_{j=1}^K \Phi[E(X_tX'_t|s_t = j)Pr(s_t = j|s_{t+1} = i)]\Phi' \\ &= G(i) + \sum_{j=1}^K b_{ij}\Phi E(X_tX'_t|s_t = j)\Phi' \end{aligned}$$

Taking vec's of both sides, we obtain:

$$\text{vec}(E(X_{t+1}X'_{t+1}|s_{t+1} = i)) = \text{vec}(G(i)) + (\Phi \otimes \Phi) \sum_{j=1}^K \text{vec}(E(X_tX'_t|s_t = j))b_{ij} \quad (\text{G-8})$$

If we define the $KN^2 \times 1$ vectors:

$$\vec{E}(X_tX'_t|s_t) = \begin{bmatrix} \text{vec}(E(X_{t+1}X'_{t+1}|s_{t+1} = 1)) \\ \vdots \\ \text{vec}(E(X_{t+1}X'_{t+1}|s_{t+1} = K)) \end{bmatrix} \quad \text{and} \quad \vec{G} = \begin{bmatrix} \text{vec}(G(1)) \\ \vdots \\ \text{vec}(G(K)) \end{bmatrix}$$

we can write (G-8) as:

$$\vec{E}(X_tX'_t|s_t) = \vec{G} + (\Phi \otimes \Phi)\vec{E}(X_tX'_t|s_t)B'.$$

Hence, we can solve for $\vec{E}(X_tX'_t|s_t)$ as:

$$\text{vec}[\vec{E}(X_tX'_t|s_t)] = (I_{KN^2} - B \otimes (\Phi \otimes \Phi))^{-1} \text{vec}[\vec{G}]. \quad (\text{G-9})$$

Unconditional Moments

The first unconditional moment $E(X_t)$ is solved simply by taking unconditional expectations of (2), giving

$$E(X_t) = (I - \Phi)^{-1} \sum_{i=1}^K \pi_i \mu(i). \quad (\text{G-10})$$

To solve the second unconditional moment $\text{var}(X_t)$, we use:

$$\begin{aligned} \text{var}(X_t) &= E(X_tX'_t) - E(X_t)E(X_t)' \\ &= E(E(X_tX'_t|s_t)) - E(X_t)E(X_t)' \\ &= \sum_{i=1}^K \pi_i \{ \text{var}(X_t|s_t = i) + E(X_t|s_t = i)E(X_t|s_t = i)' \} - E(X_t)E(X_t)' \end{aligned} \quad (\text{G-11})$$

Moments of Yields

Bond yields are affine functions of X_t , from Propositions B.1 and C.1. Hence, they can be written as $Y_t = A(S_t) + BX_t$ for some choice of $A(S_t)$ and B . Then, regime-dependent moments of Y_t are given by:

$$\begin{aligned} E(Y_t|s_t) &= A(S_t) + BE(X_t|s_t) \\ \text{var}(Y_t|s_t) &= B\text{var}(X_t|s_t)B', \end{aligned} \quad (\text{G-12})$$

and the unconditional moments of Y_t are:

$$\begin{aligned} E(Y_t) &= \sum_{i=1}^K \pi_i E(Y_t | s_t = i) \\ \text{var}(Y_t) &= E(Y_t Y_t') - E(Y_t) E(Y_t)' \\ &= E(E(Y_t Y_t' | S_t)) - E(Y_t) E(Y_t)' \\ &= \sum_{i=1}^K \pi_i \{ \text{var}(Y_t | S_t) + E(Y_t | S_t) E(Y_t | S_t)' \} - E(Y_t) E(Y_t)' \end{aligned} \tag{G-13}$$

Table 1: Nomenclature of Models

	Regime-Switching Models				
	Affine	Two Regimes	Three Regimes	Four Regimes	Six Regimes
3-Factor Models	I	II	III	IV^A, IV^B, IV^C	VI
4-Factor Models	I_w	II_w	–	IV_w^A, IV_w^B, IV_w^C	–

This table summarizes the models estimated. The affine models are single regime models. In the two and three regime models, the real rate factor and inflation share the same regimes, so $s_t = s_t^f = s_t^\pi$, which take values from $\{1, 2\}$ or $\{1, 2, 3\}$, respectively. In the four and six regime models, the regimes s_t reflect switches in both s_t^f and s_t^π . In the four-regime model, $s_t^f \in \{1, 2\}$ and $s_t^\pi \in \{1, 2\}$, and the probability transition matrix can be one of three cases, independent (Case A) and correlated cases B and C, which are outlined in Section 2.4. In the six-regime model, $s_t^f \in \{1, 2\}$ and $s_t^\pi \in \{1, 2, 3\}$, and s_t^f and s_t^π are independent. The three-factor models contain the factors $X_t = (q_t f_t \pi_t)'$ with q_t a time-varying price of risk factor, f_t is a latent RS term structure factor, and π_t is inflation. The dynamics of X_t are outlined in Section 2.2. The models denoted with w subscripts also contain an additional factor representing expected inflation. These models are described in Appendix E.

This table reports moment and residual tests of inflation (Panel A) and of yields (Panel B), which are outlined in Appendix F. In the columns titled “Moment Tests,” we report the p-values of goodness-of-fit χ^2 tests for various moments implied by the different models. In Panel A, the first moment test matches the mean and variance of inflation, whereas in Panel B, the first moment test matches the mean and variance of the long rate and the spread jointly. The long rate refers to the 20-quarter nominal rate y_t^{20} and the spread refers to $y_t^{20} - y_t^1$, for y_t^1 the 3-month short rate. The second autocorrelogram moment test matches autocorrelations at lags 1, 5, and 10. The columns titled “Residual Tests” report p-values of scaled residual tests for the different models. The first entry reports the p-value of a test of $E(\epsilon_t \epsilon_{t-1}) = 0$ and the second row reports the p-value of a GMM-based test of $E[(\epsilon_t^2 - 1)(\epsilon_{t-1}^2 - 1)] = 0$, where ϵ_t is a scaled residual. P-values less than 0.05 (0.01) are denoted by * (**). Table 1 contains a nomenclature of the various models.

0.050 (0.003)	0.024 (0.001)

The table reports estimates of the benchmark RS model IV^C with correlated s_t^f and s_t^π regimes outlined in Section 2. The stable probabilities of regime 1 to 4 are 0.725, 0.039, 0.197, and 0.038, with standard errors of 0.081, 0.029, 0.052, and 0.018, respectively. We reject the null of independent regimes (Case A) with a p-value of 0.033 using a likelihood ratio test.

Table 4: Factor Behavior

Panel A: Moments of Factors									
	Stdev	Auto	Contribution to Real Rate Variance	Contribution to Expected Inflation Variance	Correlation with				
					Inflation	Nominal Short Rate	Nominal Spread	Real Short Rate	Real Spread
q	1.70 (0.55)	0.98 (0.01)	0.51 (0.35)	0.28 (0.08)	0.61 (0.11)	0.90 (0.05)	-0.20 (0.07)	0.44 (0.21)	-0.09 (0.02)
f	0.68 (0.20)	0.74 (0.02)	0.09 (0.10)	0.09 (0.05)	0.24 (0.07)	0.43 (0.11)	-0.99 (0.02)	0.19 (0.17)	-0.24 (0.17)
π	3.50 (0.42)	0.76 (0.05)	0.40 (0.36)	0.62 (0.08)	1.00 -	0.69 (0.08)	-0.44 (0.06)	-0.34 (0.29)	0.59 (0.12)
Data π	3.16	0.72				0.68	-0.37		

Panel B: Projection of Inflation on Lagged Instruments			
	Inflation	Nominal Short Rate	Nominal Spread
Model	0.52 (0.06)	0.39 (0.07)	-0.08 (0.17)
Data	0.49 (0.06)	0.29 (0.07)	-0.39 (0.15)

The table reports various unconditional moments of the three factors: the time-varying price of risk factor q_t , the RS factor f_t and inflation π_t , from the benchmark model IV^C . The short rate refers to the 1-quarter nominal yield and the spread refers to the 20-quarter nominal term spread. The row labelled 'Data π ' refers to actual inflation data. The numbers between parentheses are standard errors reflecting parameter uncertainty from the estimation, computed using the delta method. The variance decomposition of the real rate is computed as $\text{cov}(r_t, z_t)/\text{var}(r_t)$, with z_t respectively q_t , f_t and $\delta_\pi \pi_t$. The variance decomposition of expected inflation is computed as $\text{cov}(E_t[\pi_{t+1}], z_t)/\text{var}(E_t[\pi_{t+1}])$, with z_t respectively $\Phi_{\pi q} q_t$, $\Phi_{\pi f} f_t$, and $\Phi_{\pi \pi} \pi_t$. Panel B reports multivariate projection coefficients of inflation on the lagged short rate, spread and inflation implied by the model and in the data. Standard errors in parenthesis are computed using the delta method for the model-implied coefficients and are computed using GMM for the data coefficients.

Table 5: Real Rates, Inflation Compensation, and Nominal Rates Across Regimes

		Regime			
		$s_t = 1$	$s_t = 2$	$s_t = 3$	$s_t = 4$
Real Short Rate \hat{r}_t	Mean	1.14 (0.39)	1.98 (0.53)	1.34 (0.35)	1.97 (0.45)
	Std Dev	1.40 (0.22)	1.55 (0.29)	1.55 (0.25)	1.68 (0.29)
Real Term Spread $\hat{y}_t^{20} - \hat{r}_t$	Mean	0.15 (0.31)	-0.39 (0.21)	-0.03 (0.28)	-0.45 (0.16)
	Std Dev	1.12 (0.17)	1.26 (0.25)	1.31 (0.22)	1.42 (0.25)
Inflation Compensation $\pi_{t,1}^e$	Mean	3.92 (0.38)	2.46 (0.79)	4.43 (0.39)	3.20 (0.67)
	Std Dev	2.75 (0.50)	2.95 (0.51)	3.01 (0.48)	3.13 (0.49)
Nominal Short rate r_t	Mean	5.06 (0.08)	4.45 (0.38)	5.77 (0.17)	5.17 (0.34)
	Std Dev	3.04 (0.74)	3.12 (0.73)	3.47 (0.65)	3.50 (0.65)

We report means and standard deviations for real short rates, \hat{r}_t ; the 20-quarter real term spread, $\hat{y}_t^{20} - \hat{r}_t$, 1-quarter ahead inflation compensation, $\pi_{t,1}^e$; and nominal short rates, r_t , implied by model IV^C across each of the four regimes. The regime $s_t = 1$ corresponds to $(s_t^f = 1, s_t^\pi = 1)$, $s_t = 2$ to $(s_t^f = 1, s_t^\pi = 2)$, $s_t = 3$ to $(s_t^f = 2, s_t^\pi = 1)$ and $s_t = 4$ to $(s_t^f = 2, s_t^\pi = 2)$. Standard errors reported in parentheses are computed using the delta method.

Table 6: Characteristics of Real Rates

Panel A: Conditional Moments										
Maturity Qtrs	Regime $s_t = 1$		Regime $s_t = 2$		Regime $s_t = 3$		Regime $s_t = 4$

Note to Table 6

The table reports various moments of the real rate, implied from model IV^C . Panel A reports the conditional mean and standard deviation of real rates of various maturities in quarters across regimes. Panel B reports the unconditional mean, standard deviation and autocorrelation of real yields. Panel C reports the correlation of real yields with actual and unexpected inflation implied from the model. We report the conditional correlation of real yields with actual inflation $\text{corr}(\hat{y}_{t+1}^n, \pi_{t+1} | s_t)$, and the conditional correlation of real yields with expected inflation $\text{corr}(\hat{y}_{t+1}^n, E_{t+1}(\pi_{t+1+n,n}) | s_t)$. Standard errors reported in parentheses are computed using the delta method.

Table 7: Effect of Regimes on Real Rates

Panel A: Real Yield Characteristics			
		Model I_w	Model IV^C
Real Short Rate \hat{r}_t	Mean	1.42 (0.31)	1.24 (0.38)
	St Dev	1.59 (0.29)	1.46 (0.23)
	Auto	0.72 (0.09)	0.60 (0.08)
Real Long Rate \hat{y}_t^{20}	Mean	1.69 (0.30)	1.32 (0.40)
	St Dev	1.04 (0.34)	0.55 (0.32)
	Auto	0.96 (0.02)	0.94 (0.05)
Correlation $\hat{r}_t, \hat{y}_t^{20}$		0.79 (0.08)	0.64 (0.06)
Panel B: Comparisons of I_w and IV^C over the Sample			
Real Short Rate \hat{r}_t Differences	Std Dev	1.40	
	Min	-2.61	
	Max	6.01	
Real Long Rate \hat{y}_t^{20} Differences	Std Dev	0.54	
	Min	-1.06	
	Max	1.85	

The table reports various characteristics of real yields from model I_w , an affine model similar to Campbell and Viceira (2001), and our model IV^C . In Panel A, we report population means, standard deviations, and autocorrelations of real one-quarter short rates and real 20-quarter long yields, together with their correlation. Standard errors reported in parentheses are computed using the delta method. In Panel B, we report statistics on the differences between the real yields implied by model I_w and model IV^C over the sample.

Table 8: Inflation Compensation, Expected Inflation, and Inflation Risk Premiums

Qtrs	$s_t = 1$	$s_t = 2$	$s_t = 3$	$s_t = 4$	Uncondi- tional
Inflation Compensation $\pi_{t,n}^e$					
1	3.92 (0.38)	2.46 (0.78)	4.43 (0.39)	3.20 (0.67)	3.94 (0.38)
4	4.20 (0.34)	2.49 (0.70)	4.95 (0.39)	3.34 (0.59)	4.25 (0.35)
20	5.09 (0.41)	3.80 (0.45)	5.45 (0.43)	4.36 (0.42)	5.08 (0.38)
Expected Inflation $E_t(\pi_{t+n,n})$					
1	3.93 (0.38)	2.47 (0.79)	4.44 (0.39)	3.21 (0.67)	3.94 (0.38)
4	3.89 (0.38)	2.63 (0.73)	4.48 (0.41)	3.47 (0.65)	3.94 (0.38)
20	3.91 (0.38)	3.39 (0.49)	4.20 (0.39)	3.82 (0.46)	3.94 (0.38)
Inflation Risk Premium $\varphi_{t,n}$					
4	0.31 (0.09)	-0.14 (0.06)	0.47 (0.15)	-0.13 (0.09)	0.31 (0.10)
20	1.18 (0.36)	0.42 (0.23)	1.25 (0.42)	0.55 (0.31)	1.14 (0.36)

The table reports means of inflation compensation, the difference between nominal and real yields; expected inflation; and the inflation risk premium implied from the benchmark model IV^C . Standard errors reported in parentheses are computed using the delta method.

Table 9: Conditional Moments Across NBER Business Cycles

	Maturity Qtrs	Mean		Std Dev	
		Expansion	Recession	Expansion	Recession
Real Rates \hat{y}_t^n	1	1.45 (0.20)	1.23 (0.20)	1.30 (0.04)	2.06 (0.08)
	20	1.33 (0.38)	1.43 (0.38)	0.65 (0.18)	0.87 (0.25)
Nominal Rates y_t^n	1	5.03 (0.09)	5.95 (0.14)	2.59 (0.27)	4.07 (0.41)
	20	6.05 (0.20)	6.85 (0.22)	2.46 (0.26)	3.71 (0.38)
Inflation Compensation $\pi_{t,n}^e$	1	3.57 (0.19)	4.73 (0.17)	2.23 (0.18)	3.62 (0.28)
	20	4.72 (0.37)	5.42 (0.39)	1.89 (0.38)	2.93 (0.57)

The table reports various sample moments of real rates, nominal rates and inflation compensation from the benchmark model IV^C , conditional on expansions and recessions as defined by the NBER. Standard errors reported in parentheses are computed using the delta method on sample moments.

Table 10: Unconditional Variance Decomposition of Nominal Yields

Maturity Qtrs	Real Rates	Expected Inflation	Inflation Risk
1	0.20 (0.09)	0.80 (0.09)	0.00 (0.00)
20	0.20 (0.09)	0.71 (0.09)	0.10 (0.08)

The table reports unconditional variance decompositions of nominal yields, y_t^n , into real rate, expected inflation, and inflation risk premium components, denoted by \hat{y}_t^n , $E_t(\pi_{t,n})$, and $\varphi_{t,n}$, respectively, implied by model IV^C . This is done using the equation:

$$1 = \frac{\text{var}(y_t^n, y_t^n)}{\text{var}(y_t^n)} = \frac{\text{cov}(\hat{y}_t^n, y_t^n) + \text{cov}(E_t(\pi_{t,n}), y_t^n) + \text{cov}(\varphi_{t,n}, y_t^n)}{\text{var}(y_t^n)}.$$

Standard errors reported in parentheses are computed using the delta method on population moments.

Table 11: Unconditional Variance Decomposition of Nominal Yield Spreads

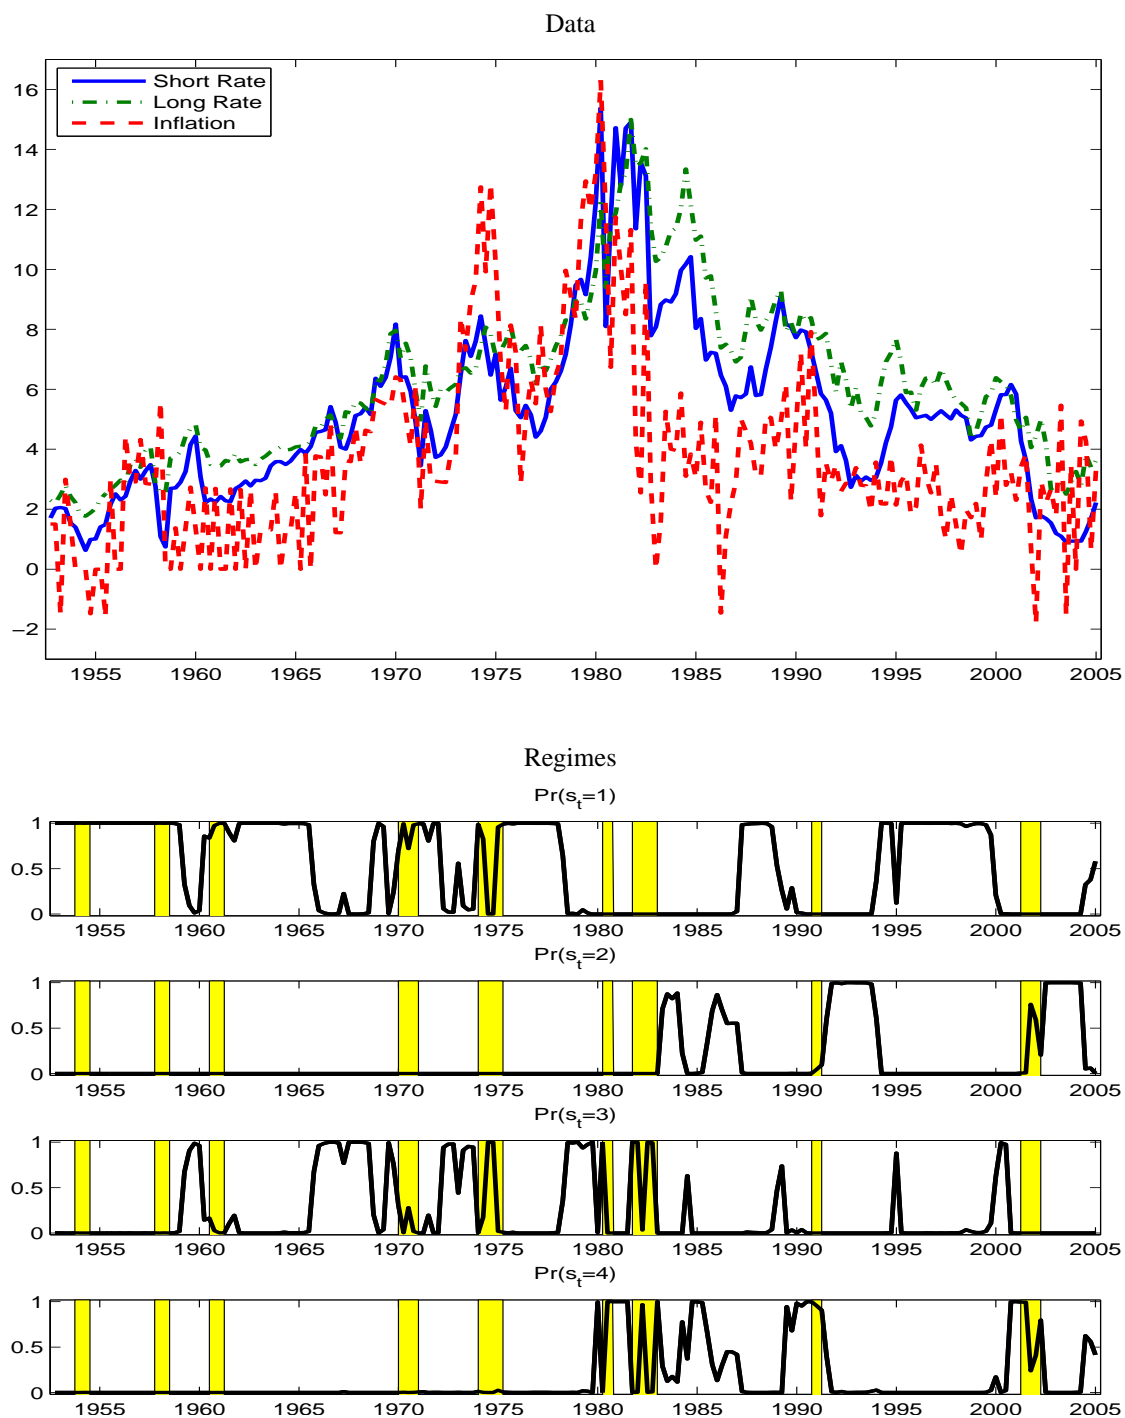

Panel A: Unconditional						
Maturity Qtrs	Real Rates	Expected Inflation	Inflation Risk			
4	0.38 (0.14)	0.49 (0.14)	-0.01 (0.00)			
20	0.20 (0.19)	0.88 (0.19)	-0.05 (0.02)			
Panel B: Conditional on Regime						
Maturity Qtrs	Real Rates	Expected Inflation	Inflation Risk	Real Rates	Expected Inflation	Inflation Risk
	Regime $s_t = 1$			Regime $s_t = 2$		
4	0.14 (0.19)	0.87 (0.19)	-0.01 (0.00)	0.08 (0.22)	0.93 (0.22)	-0.01 (0.00)
20	0.04 (0.20)	1.03 (0.20)	-0.08 (0.03)	-0.02 (0.22)	1.07 (0.22)	-0.05 (0.03)
	Regime $s_t = 3$			Regime $s_t = 4$		
4	0.69 (0.12)	0.32 (0.12)	-0.00 (0.00)	0.64 (0.13)	0.36 (0.13)	-0.00 (0.00)
20	0.31 (0.16)	0.71 (0.16)	-0.02 (0.01)	0.29 (0.17)	0.73 (0.17)	-0.02 (0.01)

The table reports unconditional variance decompositions of nominal yield spreads, $y_t^n - y_t^1$, into real rate, expected inflation, and inflation risk premium components, denoted by $\hat{y}_t^n - \hat{r}_t$, $E_t(\pi_{t,n}) - E_t(\pi_{t+1})$, and $\varphi_{t,n}$, respectively, implied by model IV^C . This is done using the equation:

$$\begin{aligned}
 1 &= \frac{\text{var}(y_t^n - y_t^1, y_t^n - y_t^1)}{\text{var}(y_t^n - y_t^1)} \\
 &= \frac{\text{cov}(\hat{y}_t^n - \hat{r}_t, y_t^n - y_t^1) + \text{cov}(E_t(\pi_{t,n}) - E_t(\pi_{t+1}), y_t^n - y_t^1) + \text{cov}(\varphi_{t,n}, y_t^n - y_t^1)}{\text{var}(y_t^n - y_t^1)}.
 \end{aligned}$$

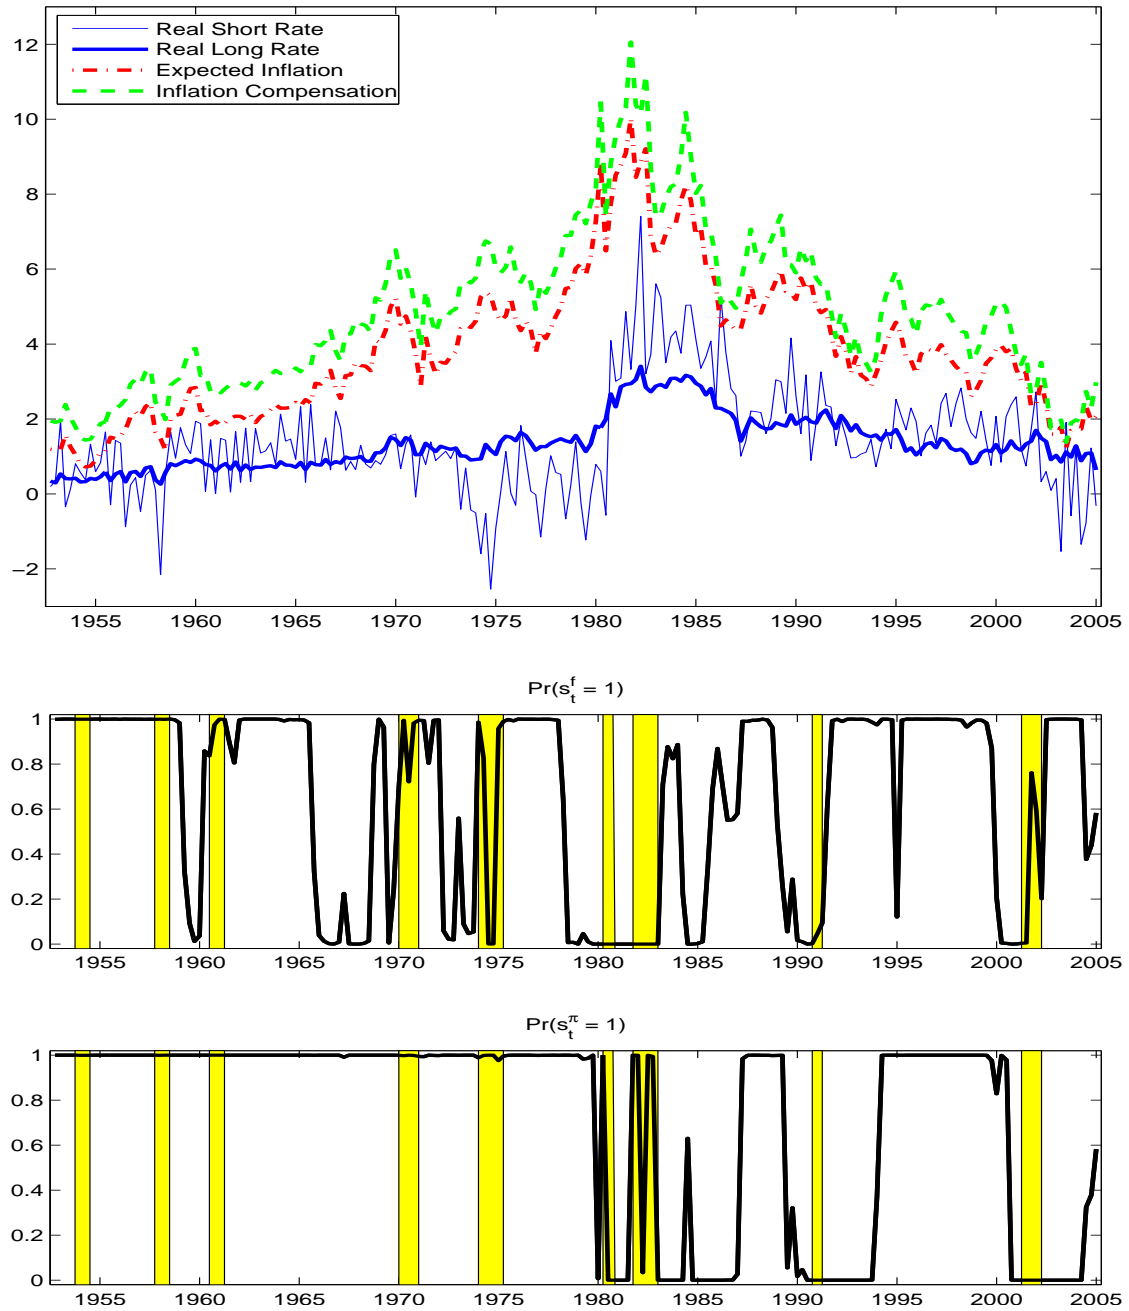

Standard errors reported in parentheses are computed using the delta method on population moments.

Figure 1: Smoothed Regime Probabilities: All Regimes

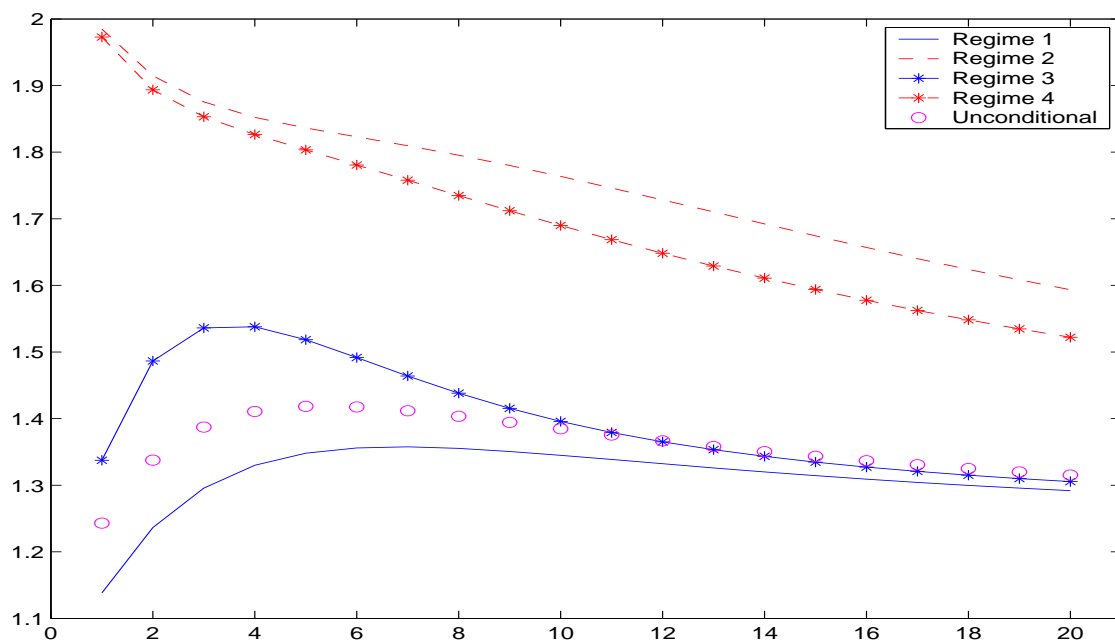

The top graph plots the nominal short rate (1-quarter yield) and nominal long rate (20-quarter yield) together with quarter-on-quarter inflation. The top panel's y -axis units are annualized and are in percentages. In the bottom graph, we plot the smoothed probabilities of each of the four regimes, $Pr(s_t = i|I_T)$, conditioning on data over the entire sample, from the benchmark model IV^C . NBER recessions are indicated by shaded bars.

Figure 2: Smoothed Regime Probabilities

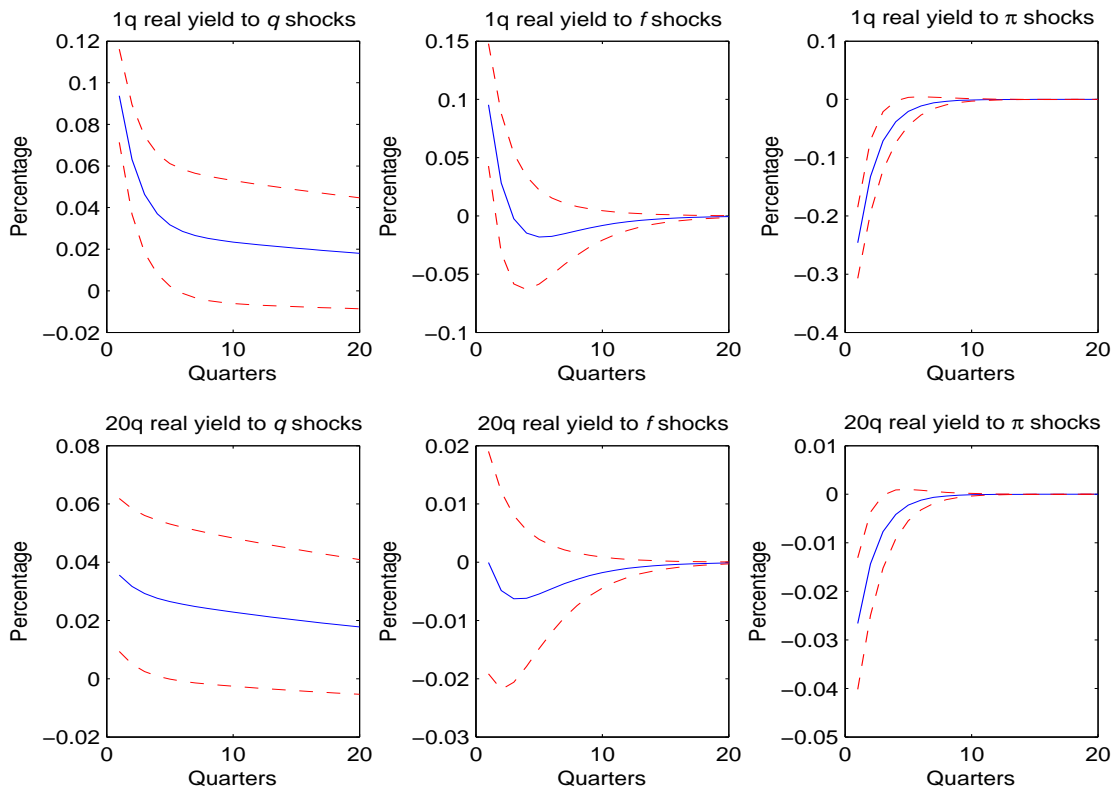

The top panel graphs the real short rate, \hat{r}_t ; real long rate, \hat{y}_t^{20} ; one-quarter expected inflation, $E_t(\pi_{t+1})$; and long-term inflation compensation, $\pi_{t,20}^e$, implied from model IV^C . The top panel's y -axis units are annualized and are in percentages. The middle and bottom panels plot smoothed regime probabilities using information from the whole sample. The middle panel shows the smoothed probabilities $Pr(s_t^f = 1|I_T)$ of the f factor regimes, s_t^f . The bottom panel graphs the smoothed probabilities $Pr(s_t^\pi = 1|I_T)$ of the inflation factor regime, s_t^π . NBER recessions are indicated by shaded bars.

Figure 3: Real Term Structure

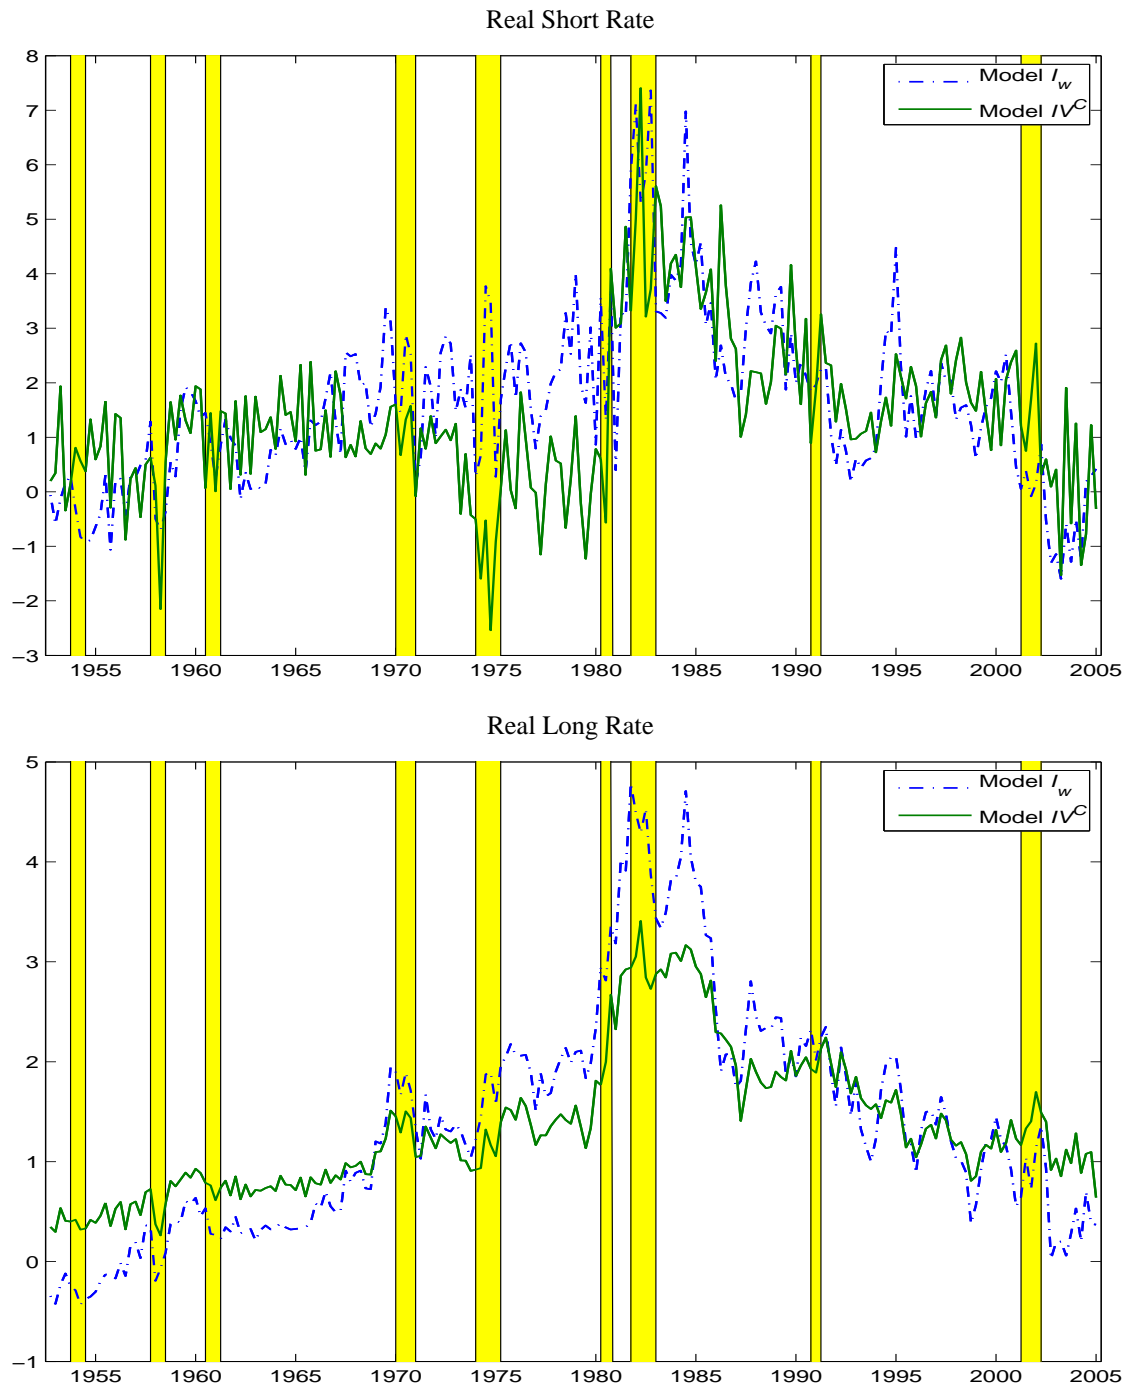

We graph the real yield curve, conditional on each regime and the unconditional real yield curve implied from model IV^C . The x -axis displays maturities in quarters of a year. The y -axis units are annualized and are in percentages.

Figure 4: Impulse Responses of Real Yields

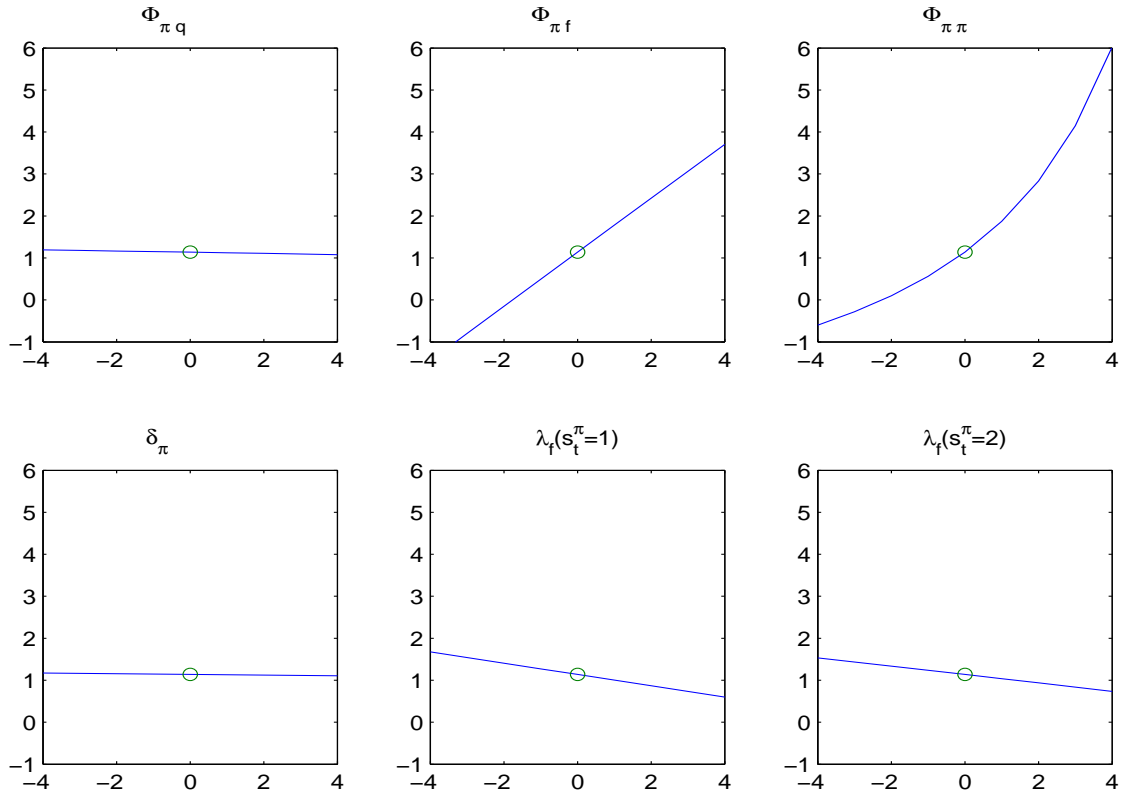

The figure plots impulse responses (IRs) of 1- and 20-quarter real yields (solid lines), together with two standard errors bands (dashed lines), as implied by model IV^C . All IRs are computed using a one standard deviation shock. The units on the y -axis are in annualized percent.

Figure 5: Comparing Benchmark Model IV^C Real Yields with Model I_w

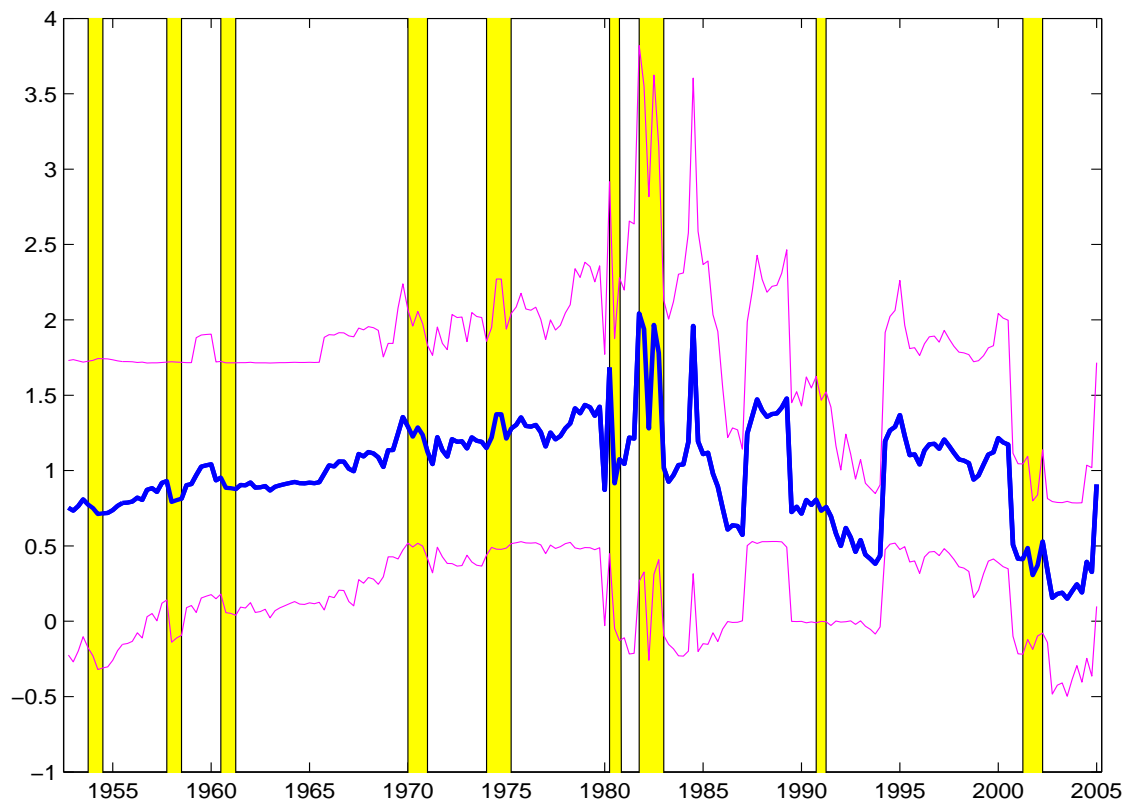

The figure compares the 1-quarter real short rate (5-year real long yield) of the benchmark model IV^C and model I_w in the top (bottom) panel over the sample period.

Figure 6: Comparative Statics of the Long-Term Inflation Risk Premium

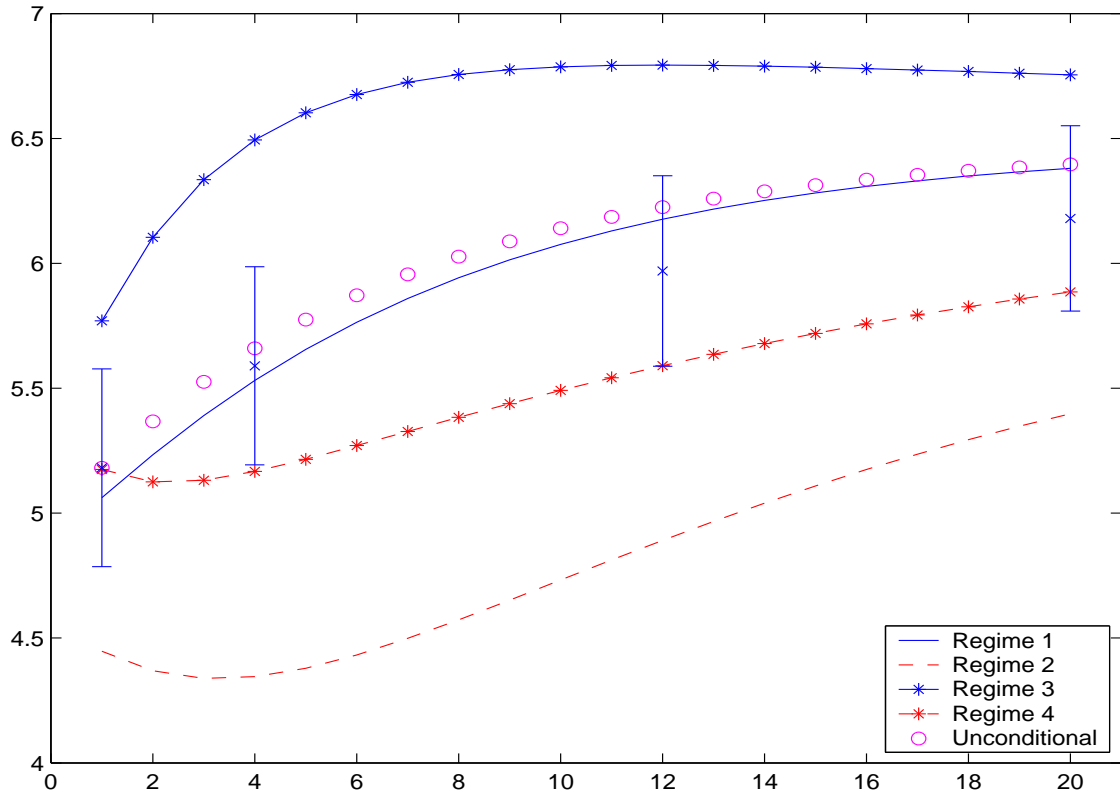

In each plot, we show the unconditional 20-quarter inflation risk premium, $\varphi_{t,20}$, as a function of various parameters of the benchmark model IV^C . The units on the y -axis are annualized and are in percentage terms, and we alter the value of each parameter on the x -axis by up to ± 4 standard errors of the estimates of each parameter. The circle represents the baseline case at the estimated parameter value, of 1.14%.

Figure 7: Inflation Risk Premiums

The figure graphs the time-series of the 20-quarter inflation risk premium, $\varphi_{t,20}$, with two standard error bounds, implied from model IV^C . NBER recessions are indicated by shaded bars.

Figure 8: Nominal Term Structure

The figure graphs the nominal yield curve, conditional on each regime and the unconditional nominal yield curve from the benchmark model IV^C . The x -axis displays maturities in quarters of a year. The y -axis units are annualized and are in percentages. Average yields from data are represented by 'x', with 95% confidence intervals represented by vertical bars.
