I. INTRODUCTION

Various individuals and/or organizations have predicted a dark future for the commercial television networks and by association for over-the-air commercial television broadcasters as a result of the increased competition broadcasters are facing (will face) from new forms of video program delivery. Most of the prophecies of doom stem from declines in network prime time audience shares (Table I) and in local station audience shares among cable subscribers (Table II) and from expected increases in video market competition from new video delivery technologies.

A number of past empirical studies including: Fisher, et. al. (1980), Park (1979), Schink and Thanawala (1978), and Webster (1983) have clearly established that cable television has a significant negative impact on the audience levels achieved by over-the-air commercial television stations. There is little disagreement concerning cable's impact the on information/entertainment side of the video market with respect to local television stations and the television networks. The impact is negative and significant and it appears to be increasing in magnitude over time (See Tables I and II). As new forms of video delivery technology become available to expand the number of channels of video programming from which consumers can choose, a similar negative impact on television broadcast audiences can be expected to occur.

The impact of competition from cable and other new technologies on television station and television network audiences, however, does not necessarily mean that any stations

or networks will be driven out of business. In fact, increased competition on the information/entertainment side of the video marketplace may not even cause a decrease in the profitability of television stations and networks. This is because cable and various forms of pay television delivery do not provide meaningful competition for television broadcasters on the advertising side of the video marketplace at this time.

If television broadcasters continue to possess a significant amount of market power on the advertising side of the market, broadcasters may be able to increase the price per thousand or per rating point for which they sell their audience to advertisers to maintain revenue levels in spite of significant audience decline. To the extent that local television stations and the television networks are viewed by advertisers as "must buys" with respect to reaching a mass audience and to the extent that television broadcasters continue to operate in oligopolistic advertising markets, television broadcast revenue levels can be expected to be relatively unaffected by cable and other new delivery technologies.

The primary focus of this study will be to determine whether television broadcasters continue to operate in oligopolistic advertising markets in spite of the increased competition they face from cable and pay cable on the information/entertainment side of the video marketplace. Our empirical focus is on local television markets due to the availability of published data in this area. Although we are not able to empirically test our hypotheses with respect to the television networks, we can extend

the results obtained from our analysis to the network television advertising market.

In the next section of this chapter, we provide two alternative theoretical models for estimating the value of commercial time on local television stations: a competitive market model and an oligopolistic market model. Our empirical results are presented in Section III along with variable definitions, data sources and the estimating forms of our models. In Section IV, an assessment is made of the impact of cable and pay cable on television station revenues. The implications of our empirical results are discussed in Section V and conclusions regarding the future role of local commercial television stations and of the commercial television networks are provided in Section VI.

II. THE MODELS

In this section we develop two alternative models of the value of commercial time. The first is based on the assumption that the price paid for commercial time is determined in a competitive market for exposures to viewers with the value of a particular audience determined by the characteristics of the viewing audience. The second model is an application of oligopoly pricing with price determined by both the characteristics of the potential viewing audience and the intensity of competition in providing access to commercial broadcast time in the market.

A. The Competitive Model

The first type of model has been widely applied in

estimation of the audience-revenue relationship for television stations. A recent example is the work of Fisher, <u>et.al.</u> (1980). A general representation of the estimating equation used in these studies is

(1)
$$R/H = b_0 + b_1(V/H) + \sum_{i=1}^{H} b_{i+1}X_i$$

where

- R is the revenue received from the sale of commercial time of a particular duration (e.g., one 30 second spot) or over a period of time (e.g., one a year).
- H is the number of households in a station's viewing area with different definitions of the viewing area employed in different studies.
- V is a measure of audience size for the station during the revenue period.
- X represents a variable which affects the quality of the audience provided by the station (e.g., average household income), and
- b represents an estimated coefficient.

The coefficient of V/H in (1) provides an estimate of the price for a viewer exposure. A linear relation between R/H and V/H is used because the existence of perfect competition implies that the price charged for a viewer is independent of the number of viewers provided.¹ The X_i represent characteristics of the viewers provided by a particular station. They are generally interpreted as hedonic price function parameters, showing the

value of a particular audience characteristic to advertisers.

B. The Oligopoly Model

Our alternative model of the value of commercial time is derived from the theory of oligopoly pricing. Following the analysis of Stigler (1964), we treat the likelihood that a firm can successfully use secret price concessions to undercut its rivals as decreasing with increases in market concentration. The particular measure of concentration used by Stigler is the Herfindahl index, which is calculated as the sum of the squares of the market shares of all firms in the market. The reduced likelihood of success with secret price concessions leads to a higher expected average price level in the market. Thus, a positive relation is expected between the value of commercial time and the Herfindahl index for concentration of stations selling time in a market.² We use a log-linear function to apply the oligopoly pricing model to estimating the value of commercial time. Our estimating equations are of the general form

(2) $\log(R) = b_0 + b_1 \log(H) + b_2 \log(V/H) + b_3 \log(HI)$

$$+ \sum_{i=1}^{n} b_{i+3} \log(X_i),$$

where HI is the Herfindahl index of market concentration and all other variables have been defined above. The oligopoly pricing model implies that the value of b_3 in (2) is positive.

The difference in the dependent variable between (1) and (2) reflects a difference in the conception of the product being purchased by advertisers. In the competitive model the

product is viewer exposures, while in the oligopoly model the product is access to a particular viewing audience. This difference is subtle but critical. If the product is viewer exposures, it is reasonable to consider television stations in different local markets to be competing for the same advertising The number of sellers in the relevant market is large dollars. and perfect competition is a reasonable expectation. However, if the product is access to a particular viewing audience, the number of sellers in the relevant market is limited to the small number of stations which can reach the particular audience. This implies that viewer exposures in Chicago are not good substitutes for exposures in Denver or anywhere else, and that competition is very imperfect. Even the viewer exposures within a particular television market are imperfect substitutes because the audience delivered differs across stations and programs.

The conception of the product as access to a particular audience in (2) affects the specification of the independent variables as well as the dependent variable. We use the number of households in the viewing area, H, as the measure of the potential audience to which a station is selling access. The ratio of households viewing an individual station to total households in the viewing area, V/H, then measures the station's success in reaching the potential audience. The coefficients of both log(H) and log(V/H) are expected to be positive as both a larger potential audience and greater success in reaching that audience are valuable to advertisers.³ The log-linear form of (2) means that the coefficients of the independent variables provide estimates of the elasticity of the price of commercial

time with respect to each independent variable.

The conception of the product as access to a particular audience also affects the measurement of the Herfindahl Index. The market shares provided by rating services are shares of the total viewing audience. Those households which are viewing noncommercial local stations, cable programming or non-local market stations are not reachable through advertising on local market stations. Consequently, the relevant market share for measuring concentration in the local market is the share of viewers watching local commercial stations. The measure of the Herfindahl Index used in our regressions is the sum of the squared market shares for local commercial stations where the shares are recalculated as shares of those viewers watching only local commercial stations.

Regression equations of form (1) are not directly comparable to those of type (2). Theil (1971, 544) points out that the residual variance criterion cannot be used to choose between alternative specifications of a relationship when the left-hand variable is not the same in each specification. We can, however, test the estimated coefficients of regressions of type (2) for consistency with either the competitive pricing model or the oligopoly pricing model.

In the competitive pricing model market concentration as measured by the Herfindahl index does not affect the price paid for commercial time, because competition from other media or markets is sufficient to keep price to the competitive level with or without concentration. This implies a value of zero for

 b_3 in (2), rather than the greater than zero value implied by the oligopoly pricing model. If it is possible to reject the hypothesis that b_3 is equal to zero while simultaneously it is not possible to reject the hypothesis that b_3 is greater than zero, we have clear empirical support for the oligopoly pricing model over the competitive model. If we can reject the hypothesis that b_3 is greater than zero but not the hypothesis that b_3 equals zero, we have empirical support for the competitive pricing model over the oligopoly model.

A further test for discriminating between the competitive and oligopoly pricing models involves the estimated value for b_{γ} in regressions of type (2). In the competitive pricing model, the product sold by a station is viewer exposures. An increase in the number of viewer exposures results in a proportional increase in the value of commercial time because the price received for the product is independent of the quantity supplied by a competitive seller. This implies a value of 1.0 for b₂ in (2), rather than the greater than zero value implied by the oligopoly pricing model. If we can reject either the hypothesis that b_2 is equal to 1.0 or the hypothesis that b_2 is greater than zero while not rejecting the other hypothesis, we again have a clear indication of consistency with one pricing model but not the other. The only limitation to such a test is that it is clearly biased in favor of the oligopoly pricing model because any estimated value of b, that is consistent with the hypothesis that b, equals 1.0 is necessarily consistent with the hypothesis that \mathbf{b}_2 is greater than zero.

III. REGRESSION RESULTS

The results from applying regression equations of types (1) and (2) to data for a sample of 105 television stations are given in Tables IV and V. The variable definitions and data sources are given in Table III. The sample of stations used in the regressions includes all CBS affiliated stations for which spot prices were available from <u>SRDS</u>: <u>Spot Television Rates and</u> <u>Data</u>, thereby limiting the range of factors affecting the value of commercial time on the stations.⁴ We focus on the relationship between the highest rate charged by each station for a 30 second spot and the audience attracted by M.A.S.H., the highest rated one-half hour program for the average CBS affiliate in November 1982, for this same purpose.

The regression results in Table IV have low explanatory power and reliability as indicated by the low values of the corrected R^2 's and t-ratios. This contrasts sharply with the results of prior studies employing the competitive model, such as those of the FCC (1980) and Fisher, <u>et. al.</u> (1980). We attribute our lower explanatory power and reliability to the different nature of the regression samples. We have purposely limited the variation in network affiliation and programming which accounts for much of the explanatory power in the prior studies. Thus, it is inappropriate to conclude that the competitive model should be rejected solely on the basis of the results in Table IV.

Our test for choosing between the competitive and oligopoly models is based instead on the results provided in Table V. The coefficients of log(HI), the Herfindahl Index, are all positive and significantly greater than zero at the 1% level using a one-

tailed t-test. A significantly positive impact on price is expected in the oligopoly pricing model, but not in the competitive model. Furthermore, the estimated coefficients of log(V/H), the ratio of viewers to households for the DMA, are positive but significantly less than 1.0 at the 1% level using a one-tailed t-test.⁵ In the competitive model, increases in viewers supplied to advertisers are expected to lead to proportional increases in the value of commerical time. In contrast, the oligopoly pricing model implies only that the coefficient of V/H is greater than zero. Thus we find empirical support for the oligopoly pricing model but none for the competitive pricing model.⁶

IV. THE IMPACT OF CABLE ON BROADCAST REVENUES

The traditional approach to estimating the impact of cable on the revenues of commercial broadcast stations involves two steps. First, the impact of a station's audience on its revenues is estimated using equations of type (1). Second, the impact of cable on the size and characteristics of the audience obtained by commercial stations is estimated using regressions with audience size or characteristics as the dependent variable. A recent study which nicely illustrates the two-step approach is that of Liebowitz (1982).

Our regression results suggest a critical flaw in this traditional approach. The audience-revenue relationship in equations of type (1) is based on an explicit or implicit assumption that viewer exposures are sold in a perfectly competitive market. Our results are inconsistent with the

existence of a perfectly competitive market, and instead support the interpretation that commercial broadcast time is sold in oligopolistic markets.

In our oligopolistic pricing model, competition affects a station's revenues through two variables, the station's audience share, V/H, and the level of concentration in the market for selling viewer exposures to advertisers as measured by the Herfindahl Index, HI. Since most cable systems do not currently provide significant competition for sales to advertisers, their competition extends only to the first variable (audience share). Treating the competition associated with cable offerings of distant signals and pay programming as equivalent to the competition from rival local broadcasters is therefore inappropriate. Yet, this is exactly the treatment used in the traditional approach.

The impact of both cable and other competition on broadcast revenues in the traditional approach is equal in percentage terms to their impact on the broadcast audience. In contrast, the coefficients of log(V/H) in Table V provide estimates of between .11% and .24% for the effect on revenues of a 1.0% change in audience. Thus, we estimate that the impact of cable on broadcast revenues is only one-ninth to one-fourth as large as that assumed in the traditional approach.

Liebowitz (1982) argues that cable does not reduce the advertising revenues of commercial broadcast stations, even though he uses the two-step approach for estimating cable's impact. He finds that while cable reduces the audience of broadcast stations,

it also improves the characteristics of the audience provided. He estimates the net effect on advertising revenues as approximately zero.

Our rejection of the competitive assumption implicit in the two-step approach leads us to question the validity of Liebowitz's result. Nonetheless, the argument that cable has a revenue-increasing impact on the characteristics of the audience offered by broadcast stations is plausible. This would imply that even our low estimates of the impact of cable on broadcast revenues obtained from the regressions in Table V are biased upward because we do not take account of the possible impact of cable on the characteristics of the remaining broadcast audience.

We therefore allow for a possible influence of cable on audience characteristics by adding cable penetration variables to the oligopoly pricing model regressions in Table V. The cable penetration variables measure the ratio of cable subscribers to households in the DMA, CAB/H, and the ratio of pay programming subscribers to households in the DMA, PAY/H. The results of these regressions are given in Table VI. None of the estimated coefficients of the cable penetration variables is significantly different from zero at the 10% level using a two-tailed t-test.⁷ Thus, we find no support for the hypothesis that cable penetration affects broadcast station revenue through audience characteristics.

Our final test for an effect of cable on broadcast revenues involves removing the audience variable, V/H, from the regressions in Table VI. By omitting the audience variable, we are allowing the cable penetration variables to pick up the

effect of cable on revenues which occurs either through a change in audience characteristics or through a change in audience size. The results for these regressions are given in Table VII. None of the estimated coefficients of the cable penetration variables in Table VII is significantly different from zero at the 10% level using a two-tailed t-test. Thus, when we measure the impact of cable and pay penetration on broadcast revenues directly, we find no evidence of a significant negative impact.⁸

V. IMPLICATIONS

The empirical results presented in the preceding section suggest that the increased competition television broadcasters are facing from new delivery technologies such as cable and pay television on the information/entertainment side of the video marketplace has had little impact on the market power possessed by television broadcasters on the advertiser side of the video market. This suggests that television station (and by extension television network) revenues have not been negatively affected by cable and various forms of pay program delivery. It is our belief that local television stations and the television netorks will be able to maintain their revenues (in real dollar terms) even as their audience declines, as long as new forms of video program delivery do not provide meaningful competition for television broadcasters on the advertising side of the video market. Various pieces of descriptive information gleaned from the trade press and from research reports provide support for this notion. Data provided in Bortz, et. al. (1983) and in "Broadcasters Show Profit Margin Drop" (1984) for instance

indicate that television network and television station revenues have continued to increase even in the face of declines in audience shares.

Our results suggest that increased competition from new forms of video delivery technology is not affecting television broadcast advertising revenues. However, this does not necessarily mean that cable and various forms of pay program delivery have not had an impact on broadcast television profits. To the extent that the increased competition for the television audience from various new video delivery technologies has caused the television networks and local television stations to spend an increasingly large percentage of each dollar of revenue on programming or promotion, television broadcast profit margins may well decline as a result of this increased competition.

Veronis, Shuler & Associates (VS&A) (see "Broadcasters Show Profit Margin Drop," 1984) provide descriptive data supportive of this hypothesis. Specifically, VS&A found that "pre-tax operating profit margins among 'typical' publicly traded broadcasting companies shrunk nearly 20% between 1978 and 1982" in spite of the fact that revenue growth averaged 13% during this same period." VS&A suggest that increasing costs, especially those in the programming area, were responsible for at least part of the decline in profit margins. Information provided in Bortz, <u>et. al.</u> (1983) provides support for the theory that increased competition from new technologies and/or independent television stations on the information/entertainment side of the video market is largely responsible for the decline in network profit

margins discovered by the VS&A report. FCC data contained in Bortz, et. al. (1983) indicate that the television networks experienced an average annual compound increase in advertising revenues of 13.7 percent from 1978 to 1980 while program expenses increased at an average annual compound rate of 17 percent over this same period. This finding is in sharp contrast to the "preaudience decline" revenue and program cost average annual compound growth rates experienced by the television networks from 1973 to 1977 (15.1 percent and 15.0 percent respectively). Additional information provided by Bortz, et.al. (1983) with respect to ABC-TV prime time gross revenues and prime time program costs from 1973 to 1981 is even more supportive of the theory that increased competition from cable and/or from independent television stations has caused the television networks to increase their program expenditures resulting in lower profit margins. From 1978 to 1981, ABC increased its prime time gross advertising revenues at an average compound rate of 7.9 percent. Over this same period, prime time program expenditures increased at an average compound rate of 16.6 percent. Comparable figures for average annual compound revenue and program expense growth from 1973 to 1977 are 18.2 percent and 15.5 percent respectively.

VI. CONCLUSIONS

Local television stations and the television networks face an increasingly complex and competitive marketplace with respect to vying for audience attention. As a result of this increased competition for audience, television broadcasters have

increased their program expenditures by a disproportionate amount in an attempt to reduce their loss of audience share. Utilization of such an expenditure strategy is less risky than it might otherwise be since television broadcasters and the networks are not facing any significant increase in competition for advertiser revenues. The short run result of the "program expenditure" strategy being employed by television broadcasters has been to reduce broadcaster profit margins. However, television broadcasters continue to earn above normal returns on average (see "Broadcasters Show Profit Margin Drop," 1984). Future declines in broadcast profit margins are bounded by what entrepreneurs consider to be a normal economic return with respect to television broadcasting.

The information provided in this chapter leads us to the conclusion that the television networks and local advertiser supported television stations are far from dead. As long as advertisers view television broadcast audiences as "must buys" for reaching a mass audience via television, the broadcast television business should continue to be a viable one. However, broadcast profit margins can be expected to continue their decline as television broadcasters spend an increasingly large amount of each dollar they take in attempting to maintain their audience share.⁹

FOOTNOTES

- ISome past studies employ the square of (V/H) as an explanatory variable. However, this term is not interpreted as implying a lack of competition in the sense that stations face downward sloping demand curves for viewer exposures. In the Fisher, <u>et. al.</u> (1980) study, the estimated coefficient of the squared (V/H) term is uniformly positive suggesting the implausible, i.e. that the stations face upward sloping demand curves.
- ²Stigler cites evidence closely related to our hypothesis in support of his theory. He cites a negative estimated relationship between the number of newspapers or radio stations in a market and the list price for advertising space or commercial broadcast time, respectively.
- ³If the coefficient of log(H) exceeds the coefficient of log(V/H), the cost per thousand of reaching viewers in larger markets exceeds that in smaller markets. The competitive model does not allow for the possibility that the cost per thousand viewers depends on market size. This can lead to bias in the estimated coefficient of log(HI) because market size and market concentration are highly correlated.
- ⁴The reader is referred to earlier studies of the audiencerevenue relationship for commercial television stations for results on the influence on the value of commercial time of factors such as network affiliation and time of day. See for example FCC (1980), Fisher, <u>et. al.</u> (1980) and Park

(1979). Limiting our sample to CBS affiliates and to one of the highest rated programs on these affiliates reduces the number of variables that enter the statistical analysis while still providing a sample large enough to limit the influence of sampling error.

While our conclusions below are specific to a particular network and program, this is an advantage rather than a limitation. Studies that include a wider sample are subject to bias if the influence of competition varies across categories of affiliation and programming. In contrast, our approach can be used on alternative samples to test for constancy in the estimated coefficients without introducing the possibility of bias.

- ⁵The t-ratios for the difference between 1.0 and the estimated coefficients of V/H in Table V range from 4.94 to 5.11.
- ⁶These findings contrast sharply with those of Fournier and Martin (1983). Fournier and Martin estimate an OLS regression similar to our regressions of form (2) and find a coefficient for the Herfindahl Index which is negative and not statistically significant. The Herfindahl Index in the regression is apparently calculated from market shares which have not been adjusted to eliminate the viewers of non-commercial local stations, cable programming and non-local market stations. We re-estimated the regressions in Table V substituting a Herfindahl Index based on unadjusted market shares, and found that the coefficient of the Herfindahl Index was consistently

negative and generally statistically significant at the 1% level using a two-tailed t-test. Thus, we suspect that the failure to find a positive and significant coefficient of the Herfindahl Index in the Fournier and Martin study results from inappropriate measurement of the Herfindahl Index.

- ⁷An attempt was also made to explicitly include the impact of subscription television (STV) and of Multipoint Distribution Service (MDS) competition on local station revenues by including the number of STV and the number of MDS subscribers in our pay penetration variable. The results obtained were virtually identical to those contained herein.
- ⁸This result is in contrast to Wirth and Wollert (1984) who find cable penetration had a significant negative impact on local television news prices in 1978. These different results are from regressions focused on local news advertising rates rather than prime time entertainment advertising rates.
- ⁹Note, this conclusion is not directly related to the circumstances of marginal broadcasters (small market, independent UHF, LPTV) because average returns are dominated by large market network affiliated VHF stations. The fact that cable's impact on audience improves the relative position of UHF stations (Park, 1979) suggests this group of marginal stations may not be as adversely impacted by competition.

TABLE I. TELEVISION NETWORK PRIME-TIME SHARE DECLINE IN CABLE AND PAY CABLE HOMES 1979-1982*

	T	REE NETWORK SHARE	
Year	Non-Cable Homes	Basic Cable Homes	Pay Cable Homes
1979-80	87.0%	80.5%	64.5%
1980-81	86.0	78.8	63.3
1981-82	84.5	75.3	59.3

			Estimated Coefficient of					
Constant	Log(H)	log(V/H)	log(HI)	log(SALES)	VHF	log(M/V)	\overline{R}^2	
1.889	1.028 ^b (13.52)	.238 (1.55)	.647 ^b (3.41)		<u></u>		.720	
1.094	1.054 ^b (13.18)	.229 (1.49)	.700 ^b (3.56)	.281 (1.03)			.720	
1.022	1.039 ^b (12.96)	.113 (.65)	.673 ^b (3.42)	.222 (.81)	.167 (1.40)		.723	
1.364	1.041 ^b (13.00)	.137 (.79)	.677 ^b (3.45)	.123 (.43)	.167 (1.40)	.165 (1.19)	.724	

Figures in parentheses are t-ratios.

^bIndicates coefficient is statistically significant at 1% level using a two-tailed t-test.

Estimated Coefficient of									
Constant	log(H)	log(V/H)	log(HI)	log(SALES)	VHF	log(M/V)	log(CAB/H)	log(PAY/H)	$\frac{1}{R}^2$
1.956	1.028 ^b (12.94)	.237 (1.50)	.666 ^b (3.32)				011 (.09)	.046 (.41)	.715
1.115	1.052 ^b (12.63)	.226 (1.42)	.705 ^b (3.44)	.278 (.84)			011 (.09)	.007 (.06)	.714
1.023	1.038 ^b (12.45)	.111 (.62)	.676 ^b (3.29)	.223 (.75)	.167 (1.38)		007 (.06)	.001 (.01)	.717
1.349	1.041 ^b (12.50)	.137 (.76)	.676 ^b (3.30)	.126 (.41)	.167 (1.38)	.165 (1.18)	.001 (.01)	004 (.03)	.718

TABLE VI. REGRESSION RESULTS FOR OLIGOPOLY MODEL WITH CABLE PENETRATION VARIABLE (LOG(R) DEPENDENT VARIABLE)

Figures in parentheses are t-ratios.

^bIndicates coefficient is significant at 1% level using a two-tailed t-test.

- Estimated Coefficient of								
Constant	log(H)	log(HI)	log(SALES)	VHF	log(M/V)	log(CAB/H)	Log(PAY/H)	$\frac{1}{R^2}$
1.761	1.021 ^b (12.80)	.722 ^b (3.64)	9		,	047 (.41)	.049 (.43)	.711
.835	1.047 ^b (12.53)	.763 ^b (3.77)	.309 (1.04)			045 (.39)	.006 (.05)	.711
.896	1.034 ^b (12.48)	.692 ^b (3.41)	.224 (.76)	.202 ^c (1.90)		020 (.17)	000 (.00)	.719
1.168	1.035 ^b (12.51)	.695 ^b (3.43)	.135 (.44)	.209 ^C (1.96)	.152 (1.09)	015 (.13)	006 (.05)	.719

TABLE VII.FURTHER REGRESSION RESULTS FOR OLIGOPOLY MODEL WITH
CABLE PENETRATION VARIABLES (LOG(R) DEPENDENT VARIABLE)

÷.

Figures in parentheses are t-ratios.

^bIndicates coefficient is significant at 1% level using a two-tailed t-test.

^CIndicates coefficient is significant at 5% level using a two-tailed t-test.

TABLE I. TELEVISION NETWORK PRIME-TIME SHARE DECLINE IN CABLE AND PAY CABLE HOMES 1979-1982*

1

THREE NETWORK SHARE Please note: Table III was changed Pay Cable Homes Year and is included in these tables on bond paper. Tables I, II, IV, V, 64.5% 1979 VI, and VII are the same as with the first report and you already have 63.3 1980 them on bond paper. do not de matule 59.3 1981MW * The Nielsen Co., National issues, as found in Tel Bortz, et. al. (1983).
